Abstract

We propose a new approach to modeling the cost of information structures in rational inattention problems: the “neighborhood-based” cost functions. These cost functions have two properties that we view as desirable: they summarize the results of a sequential evidence accumulation problem, and they capture notions of “perceptual distance.” The first of these properties is connected to an extensive literature in psychology and neuroscience, and the second ensures that neighborhood-based cost functions, unlike mutual information, make accurate predictions about behavior in perceptual experiments. We compare the implications of our neighborhood-based cost functions with those of the mutual information in a series of applications: security design, global games, modeling perceptual judgments, and linear-quadratic-Gaussian settings.

1 Introduction

In models of rational inattention (proposed by Christopher Sims and surveyed in Sims (2010)), a decision maker (DM) chooses her action based on a signal that provides only an imperfect indication of the true state. The information structure that generates this signal is optimal, in the sense of allowing the best possible state-contingent action choice, net of a cost of information. In Sims’ theory, the cost of any information structure is proportional to the Shannon mutual information between the true state of the world and the signals generated by that information structure.

It is not obvious, though, that the theorems that justify the use of mutual information in communications engineering (Cover and Thomas (2012)) provide any warrant for using it as a cost function in a theory of attention allocation, either in the case of economic decisions or that of perceptual judgments. Moreover, the mutual-information cost function has implications that are unappealing on their face, and that seem inconsistent with evidence on the nature of sensory processing, as discussed, for example, in Woodford (2012), Caplin and Dean (2013), Dewan and Neligh (2017), and Caplin et al. (2018b).

We propose an alternative family of information costs, which we call “neighborhood-based” cost functions. These information costs have two particular properties (in addition to the standard ones described in, e.g., De Oliveira et al. (2017)) that we view as desirable. First, they can be viewed as summarizing the results of a process of sequential evidence accumulation, in which each successive increment to the cumulatively available evidence is only very minimally informative. Second, these information costs can capture the idea that certain pairs of states are easy to distinguish, whereas others are difficult to distinguish. This second property allows the neighborhood-based cost functions avoid some of the prob-
lematic implications of mutual information. The two properties are connected by an object we call the “information-cost matrix function,” which encodes the difficulty of distinguishing between pairs of states and summarizes the cost of a small amount of information in the sequential evidence accumulation problem.

The neighborhood-based costs functions differ from mutual information because mutual information imposes a type of symmetry across different states of nature, so that it is equally difficult to distinguish between any two states that are equally probable ex ante. This implies that under an optimal information structure, actions differ across states only to the extent that the associated payoffs differ across those states, and action probabilities jump discontinuously when payoffs jump. An extensive experimental literature in psychophysics finds that subjects’ probabilities of making perceptual judgments (the action) vary continuously with changes in the stimulus magnitude along some dimension (the state), even when subjects are rewarded based on whether the magnitude is greater or smaller than some threshold (generating a discrete jump in payoffs). Such behavior can be optimal only if it is costly to have an information structure that generates very different signals in similar states, while making it less costly to distinguish states that are dissimilar. In other words, the information cost must capture some notion of “perceptual distance.”

Motivated by these issues, we consider the properties that a plausible cost function should satisfy. As discussed in Fehr and Rangel (2011) and Woodford (2014), a large literature in psychology and neuroscience has argued that data on both the frequency of perceptual errors and the frequency distribution of response times can be explained by models of sequential sampling. More recently, some authors have proposed that data on stochastic choice and response time in economic contexts can be similarly modeled. Consequently, one property we desire in a cost function is that it should summarize the results

---

2 See further discussion in section 5.2.
3 Additional recent examples include Krajbich et al. (2014) and Clithero (2018). Shadlen and Shohamy (2016) provide a neural-process interpretation of sequential-sampling models of choice.
of a sequential evidence accumulation process. In this paper, we begin with a continuous-time model of sequential evidence accumulation, and then show that the resulting state-contingent choice probabilities are identical to those of a static rational inattention model with a uniformly posterior-separable cost function.\footnote{For more on this class of cost functions, see Caplin et al. (2018b). Morris and Strack (2017) provide a related foundation for this class, in the special case in which there are only two possible states and signals are exogenous. Note, however, that with only two states, because beliefs must diffuse on a line, there is little distinction between “endogenous” and “exogenous” signals.} We derive this continuous time diffusion model from a discrete time model in Hébert and Woodford (2018).\footnote{In section C.1 of the Technical Appendix, we consider an extension of our results to a continuous-time evidence accumulation process with Poisson jumps (also derived in Hébert and Woodford (2018)), as in the models of optimal evidence accumulation proposed by Che and Mierendorff (2017) and Zhong (2018). For a discussion of the differences between these approaches, see Hébert and Woodford (2018).}

The use of diffusion processes to model the evolution of an internal belief state has been popular in the aforementioned literature from mathematical psychology and computational neuroscience, and in the economic applications reviewed by Fehr and Rangel (2011). In that literature, however, it is common to take as exogenous both the dynamics of the belief state as a function of the true decision situation, and the criterion used to decide when to stop deliberating and make a decision. Our goal instead is to derive both the nature of instantaneous evidence accumulation (and hence the dynamics of the resulting belief state) and the stopping rule (as well as the rule that determines the action to be taken) from an optimization principle, under an explicit model of the cost of information gathering.

Our paper is not the first that seeks to derive at least some features of such models from a theory of optimal information sampling. Moscarini and Smith (2001) consider both the optimal intensity of information sampling per unit of time and the optimal stopping problem, when the only possible kind of information is given by the sample path of a Brownian motion with a drift that depends on an unknown state.\footnote{Moscarini and Smith (2001) allow the instantaneous variance of the observation process to be freely chosen (subject to a cost), but this is equivalent to changing how much of the sample path of a given Brownian motion can be observed by the DM within a given amount of clock time.} Fudenberg et al. (forthcoming) consider a variant of this problem with a continuum of possible states, and an exogenously
fixed sampling intensity. Woodford (2014) instead takes as given a stopping rule, but allows a flexible choice of the information sampling process. Our approach differs from these earlier efforts in seeking to endogenize both the nature of the information that is sampled at each stage of the evidence accumulation process and the stopping rule that determines how much evidence is collected before a decision is made. We also consider decision problems with an arbitrary number of choice alternatives, as opposed to the binary choice problems of Fudenberg et al. (forthcoming) and Woodford (2014).

The key “parameter” of our diffusion model is a matrix-valued function that describes the local cost of information acquisition. If the DM chooses to have her beliefs diffuse with higher variance in some dimension, she is gathering information in this dimension, and the information-cost matrix function describes the cost of this information. It encodes, on its diagonal, how difficult each state is to learn about, and on its off-diagonal, how difficult it is to discriminate between states. Mutual information generates problematic predictions because its corresponding information-cost matrix function has a kind of symmetry that implies that equally likely states are equally difficult to discriminate.

The information-cost matrix function provides a bridge between the first property we consider desirable (equivalence to a sequential problem) and the second property (capturing perceptual distance). Given an information cost function in the sequential evidence accumulation problem, there is a static rational inattention problem with a particular uniformly posterior separable cost function that generates the equivalent joint distribution of actions and states. Moreover, the comparative statics of this joint distribution with respect to changes in payoffs are governed by the information cost matrix function. Intuitively, if the information cost matrix function makes it very costly to discriminate between some pair of states, the DM will not do so even if her payoff jumps across those states. As a result, there are uniformly posterior separable cost functions that can both summarize sequential

---

7See also Tajima et al. (2016) for analysis of a related class of models.
evidence accumulation and capture the idea of perceptual distance.

We introduce a family of such cost functions, the neighborhood-based cost functions. The idea of this class of information-cost specifications is that information structures are more costly the greater the extent to which they allow intrinsically similar states of the world (states that share a “neighborhood”) to be discriminated; the dependence on a concept of intrinsic similarity between states (the “neighborhood structure”) distinguishes these cost functions from the mutual information cost function. We show that using information costs in this family can explain the continuous variation of response frequencies in the perceptual experiments mentioned previously. Dean and Neligh (2018) study neighborhood-based cost functions in an experimental setting, and find that these costs fit observed behavior better than several other alternatives, including mutual information.

We also specialize this family to a particularly useful case, in which the states can be ordered on a line. Throughout the paper, we use as a running example the case of a potential buyer of a security whose payoff depends on the value of some assets (an example based on Yang (2017)). In this case, it is natural to suppose that the relevant states of the world are the asset values, and that it may be difficult for the DM to discriminate between nearby asset values even as the DM is more easily able to acquire information about whether the asset values will be very high or very low. We extend our analysis of this case to a continuum of states (in the rest of the paper, we use a discrete state space) and show that the limit of the neighborhood-based cost function for this neighborhood structure is the average Fisher information. This is the average value over the state space of a local measure of the discriminability of nearby states. Like mutual information, this measure is uniquely defined up to a scale parameter, and it can be used instead of mutual information in almost any context in which the states can be ordered on a line or a circle.

After we introduce the neighborhood-based cost functions, and show that they satisfy the two properties of cost functions that we view as desirable, we discuss four applications
that illustrate how they are different from or similar to mutual information. We study perceptual experiments, global games (building on Morris and Yang (2016)), security design (building on Yang (2017)), and a linear-quadratic-Gaussian setting (as in Sims (2010)). In the first three of these, the neighborhood-based cost functions generate different predictions than mutual information. In the popular linear-quadratic-Gaussian case, reassuringly, mutual information and the average Fisher information generate identical predictions.

Section 2 presents our continuous-time model of sequential evidence accumulation, and introduces the information cost matrix function as a way of parameterizing flow information costs. Section 3 proves the equivalence of sequential evidence accumulation and static rational inattention problems with uniformly posterior-separable costs. In section 4, we introduce the neighborhood-based cost functions. We apply the neighborhood-based cost functions in a series of applications in section 5. In section 6 we conclude.

2 Continuous-Time Sequential Evidence Accumulation

We begin by introducing our continuous-time model of sequential evidence accumulation. We derive this model from a discrete-time dynamic evidence accumulation problem in Hébert and Woodford (2018). Our derivation depends on a few key assumptions, whose import we discuss below. During the setup of the model, we will use as an example our security design application (Section 5.1), which is based on Yang (2017).

Let \( x \in X \) be the underlying state of the nature, and \( a \in A \) be the action taken by the decision maker (DM). For simplicity, \( A \) and \( X \) are finite sets, and the number of states is weakly larger than the number of actions, \( |X| \geq |A| \). The DM’s utility from taking action \( a \) in state \( x \) at time \( t \) is \( u_{a,x} \). The parameter \( \kappa > 0 \) governs the penalty for delaying making a decision; the DM does not discount the future.

The DM does not initially know the state \( x \in X \), but can learn about which states are
more or less likely. At each time $t$, the DM holds beliefs $q_t \in \mathcal{P}(X)$, where $\mathcal{P}(X) \subset \mathbb{R}^{|X|}$ denotes the probability simplex over $X$. That is, $q_t$ is a vector of length $|X|$, whose elements, denoted $q_{x,t}$, are the probability, under the DM’s beliefs at time $t$, of state $x$. Time begins at $t = 0$, when the DM holds prior beliefs $q_0$. At each moment in time, the DM faces two decisions: whether to gather information about the state $x \in X$, and whether to stop and make a decision. When stopping with beliefs $q_\tau$ at time $\tau$, the DM will choose $a$ to maximize $u_a^T \cdot q_\tau$, where $u_a$ is the vector of utilities associated with action $a$. Define

$$\hat{u}(q_\tau) = \max_{a \in A} u_a^T \cdot q_\tau,$$

and note that $\hat{u}(q_\tau) - \kappa \tau$ is the payoff if the DM stops with beliefs $q_\tau$ at time $\tau$ and then chooses the optimal action given those stopping beliefs.

**Example.** Suppose the DM is considering buying a security whose payoff is a function of the value of some assets. In this case, $X$ is a set of possible values for the assets, and the actions are to either accept ($L$, “like”) or reject ($R$) the offer, $A = \{L, R\}$. The utility of rejecting the offer is normalized to zero ($u_{R,x} = 0$), and the utility of accepting the offer is $u_{L,x} = s_x - K$, where $s_x$ is the security payoff and $K$ is the price. The stopping payoff $\hat{u}(\cdot)$ involves deciding, under the current beliefs, whether to accept or reject: $\hat{u}(q_\tau) = \max\{q_\tau^T s - K, 0\}$, where $s$ is the vector of security payoffs.

When the DM gathers information, she chooses the variance-covariance matrix of possible changes in her beliefs, subject to certain constraints. The DM’s beliefs evolve as

$$dq_{x,t} = q_{x,t} \sigma_{x,t} \cdot dB_t, \quad (1)$$

where $dB_t$ is an $|X|$-dimensional Brownian motion, $\sigma_t$ is a matrix that can be chosen by

---

8The $|X|$-th dimension is redundant since beliefs stay in the simplex; we keep it for notational convenience.
the DM, and $\sigma_{s,t}$ is a particular row of that matrix. This process is derived from Bayesian updating, and imposes two restrictions on the DM’s beliefs. First, beliefs are martingales, and second, $dq_{s,t} = 0$ if $q_{s,t} = 0$, meaning that if the DM believes a particular state is not possible, she will never come to believe that state is possible at some point in the future.

The DM’s choice of $\sigma_t$ is subject to restrictions — a trivial one to ensure that the beliefs stay in the simplex, and an economic restriction that limits the amount of information the DM can acquire. The trivial restriction is that

$$t^T \cdot dq_t = 0$$

always, where $t$ is a vector of ones. This restriction is equivalent to requiring that $\sigma_t^T q_t = \tilde{0}$. We will use $M(q_t)$ to denote the set of $|X| \times |X|$ matrices satisfying this condition.

The non-trivial restriction limits the quantity of information the DM can acquire:

$$\frac{1}{2} tr[\sigma_t^T k(q_t) \sigma_t] \leq \chi, \tag{2}$$

where $k(q_t)$ is an $|X| \times |X|$ dimensional matrix-valued function we will refer to as the “information-cost matrix function”, $tr[\cdot]$ is the trace, and $\chi$ is a positive constant that indexes the tightness of the constraint. We discuss this constraint, and the information-cost matrix function, in more detail below. Our derivation in Hébert and Woodford (2018) shows that the information-cost matrix function satisfies certain properties: for any $q_t$, $k(q_t)$ is symmetric and positive semi-definite, and its null space is the space of vectors that are constant for all $x \in X$ in the support of $q_t$. Because the information cost matrix function $k(q_t)$ is strictly positive-definite outside of this space, every matrix $\sigma_t \in M(q_t)$ that generates volatility in beliefs also generates a strictly positive value for $tr[\sigma_t^T k(q_t) \sigma_t]$.\(^9\)

\(^9\)Lemma 1 below proves (among other things) this fact.
Using her control of the volatility of her beliefs, and subject to the constraints imposed by the information-cost matrix function, our DM attempts to maximize her expected payoff. Her sequence problem can be written, given beliefs \( q_t \) at time \( t \),

\[
V(q_t) = \sup_{\{\sigma_t \in M(q_t)\}} E_t [\hat{u}(q_\tau) - \kappa(\tau - t)],
\]

where \( \tau \) is the DM’s endogenous stopping time, subject to the constraint (2).

Anywhere this value function is twice-differentiable and the DM does not choose to stop, the Hamilton-Jacobi-Bellman (HJB) equation associated with this problem is

\[
\sup_{\sigma_t \in M(q_t)} \frac{1}{2} \text{tr}[\sigma_t^T \text{Diag}(q_t) V_{qq}(q_t) \text{Diag}(q_t) \sigma_t] = \kappa, \\
\text{subject to } \frac{1}{2} \text{tr}[\sigma_t^T k(q_t) \sigma_t] \leq \chi,
\]

where \( \text{Diag}(q_t) \) is a diagonal matrix with the elements of \( q_t \) on its diagonal, and \( V_{qq}(q_t) \) is the Hessian of \( V(q) \) evaluated at \( q = q_t \).\(^{10}\)

The DM’s optimal stopping rule is characterized by the standard value-matching and smooth-pasting conditions. Let \( \Omega \subset \mathcal{P}(X) \) be the open subset of the simplex on which the DM continues to search for information, and let \( \partial \Omega \) denote its boundary. For all \( q \in \partial \Omega \), the value matching condition, \( V(q) = \hat{u}(q) \), and smooth pasting condition, \( V_q(q) = \hat{u}_q(q) \), will hold. Note, however, that the derivative \( \hat{u}_q(q) \) does not exist everywhere — at beliefs where the DM is just indifferent between two actions with distinct state-contingent payoffs, the stopping payoff is non-differentiable.\(^{11}\) However, it will never be optimal for the DM

\(^{10}\)The function \( V(q) \) is defined on the probability simplex \( \mathcal{P}(X) \), but we find it convenient to extend it to the space of measures, \( \mathbb{R}_+^{[X]} \), by assuming it is homogeneous of degree one. This assumption does not restrict the function’s values on the simplex. Under this assumption, vectors in the tangent space are simply vectors in \( \mathbb{R}^{[X]} \), which we express using the natural set of basis vectors corresponding to each element of \( X \). The Hessian matrices appearing in equations such as (3) above and (10) below should be understood in this way.

\(^{11}\)We have yet to show that \( V(q) \) is differentiable everywhere, but prove this as part of Theorem 1.
to stop at one of these indifference points.

Next, we provide some intuition for the volatility constraint and the information-cost matrix function. The constraint is a limit on the information the DM can acquire, because it limits the volatility of her beliefs. Our DM is a Bayesian, meaning that she can never expect to revise her beliefs in a particular direction — her beliefs must be a martingale; this is why there can be no drift term in equation (1). If she receives a mostly uninformative signal at a particular moment, her beliefs have a small amount of volatility at that moment. In contrast, if she receives an informative signal, her beliefs will be very volatile.

We derive the information constraint (2) from a model in which the DM can choose any information structure each time period, as in standard rational inattention models. One result of our derivation is that the DM can choose any volatility matrix $\sigma_t$. This is, in a sense, a familiar idea — Kamenica and Gentzkow (2011), for example, emphasize the idea of choosing a distribution of posteriors, subject to the constraint that the mean posterior is equal to the prior. Our DM appears to choose only the volatility, and not the higher cumulants of the distribution of posteriors, but this is because she finds it optimal to smooth her information gathering over time, and the instantaneous volatility is sufficient to characterize the resulting process for beliefs. This result permits both a relatively parsimonious specification of the information sampling strategies available to the DM, and a relatively parsimonious specification of possible forms for the information constraint.

Because we model the evolution of the DM’s beliefs as a diffusion process, our model resembles, e.g., Krajbich et al. (2014) and Fudenberg et al. (forthcoming). Unlike those authors, we endogenize the diffusion process through which additional information arrives while sampling continues. Additionally, our model emphasizes the “unconditional” dynamics of beliefs (that is, not conditional on any particular state being the true state), whereas the models discussed by those authors are described in terms of their “conditional” dynamics (that is, conditional on some particular state being the true state).
The information-cost matrix function \( k(q_t) \) is more than simply a way of obtaining a single (scalar) measure of the “size” of the elements of \( \sigma_t \). The relative size of different elements of the matrix also allows us to specify the degree to which it is more relatively costly to obtain certain kinds of information. In Hébert and Woodford (2018), we construct the matrix function \( k(q) \) from the cost of receiving signals about the different states. The diagonal elements \( k_{xx} \) control the cost of receiving signals, conditional on the true state being \( x \), that differ from the unconditional distribution of signals. The elements \( k_{xx} \) are always positive, and the larger they are, the more costly it is to distinguish the state \( x \) from the other states. The off-diagonal elements, \( k_{xx'} \), control the cost of receiving signals conditional on state \( x \) that differ from the signals received conditional on \( x' \). If \( k_{xx'} < 0 \), receiving similar signals conditional on \( x \) and \( x' \) reduces the overall information cost, and the magnitude of \( k_{xx'} \) controls the size of this effect. For this reason, we think of \( -k_{xx'} \) as a measure of how difficult the states \( x \) and \( x' \) are to discriminate.\(^{12}\)

An example of an information-cost matrix function that satisfies our assumptions (and will be important for the discussion below) is the “inverse Fisher information matrix,”

\[
 k(q) = g^+(q) = \text{Diag}(q) - qq^T = \begin{bmatrix}
 q_1(1 - q_1) & -q_1 q_2 & \cdots & -q_1 q_{|X|} \\
 -q_1 q_2 & q_2(1 - q_2) & \cdots & -q_2 q_{|X|} \\
 \vdots & \vdots & \ddots & \vdots \\
 -q_1 q_{|X|} & -q_2 q_{|X|} & \cdots & q_{|X|}(1 - q_{|X|})
\end{bmatrix}.
\]

In this case, the off-diagonal element \( k_{xx'}(q) \) is equal to \(-q(x)q(x')\) for any pair of states \( x, x' \); thus it depends only on the prior probabilities of the two states, and is otherwise the same regardless of the states selected. Consequently, all pairs of distinct states with identical probabilities are assumed to be equally easy or difficult to tell apart. While this

\(^{12}\)If \( k_{xx'} > 0 \), receiving very different signals conditional on \( x \) and \( x' \) reduces the information cost. We cannot rule this out on theoretical grounds, but none of our examples feature positive off-diagonal elements.
kind of symmetry might seem appealing on a priori grounds for some applications, we view it as implausible for many cases of economic relevance.

**Example.** Continuing the example of a buyer considering a security, suppose the buyer’s current beliefs $q_t$ are uniformly distributed over the various asset values $x \in X$. If $k(q)$ is the inverse Fisher information matrix, the buyer finds it equally costly to discriminate between any pair of asset values $x,x'$, regardless of how close or far apart those asset values are.

In many applications, we have a notion of some pairs of states $x,x'$ being closer or farther apart than others. In the case of payoffs, quantities, or other economic variables that can be summarized by a single number, we usually think that it is harder to sharply discriminate between values that are close together than values that are far apart. Perceptual experiments, in which subjects are asked to classify stimuli that differ from one another in intensity or magnitude along a single dimension, are another application with this feature.

An alternative information-cost matrix function, also satisfying our assumptions, is

\[
k(q) = \begin{bmatrix}
\frac{q_1 q_2}{q_1 + q_2} & -\frac{q_1 q_2}{q_1 + q_2} & 0 & \ldots & 0 \\
-\frac{q_1 q_2}{q_1 + q_2} & \frac{q_1 q_2}{q_1 + q_2} + \frac{q_2 q_3}{q_2 + q_3} & -\frac{q_2 q_3}{q_2 + q_3} & \ddots & \vdots \\
0 & -\frac{q_2 q_3}{q_2 + q_3} & \ddots & \ddots & 0 \\
\vdots & \ddots & \ddots & \ddots & 0 \\
0 & \ldots & 0 & -\frac{q_{|X|-1} q_{|X|-2}}{q_{|X|-2} + q_{|X|-1}} - \frac{q_{|X|-1} q_{|X|-1}}{q_{|X|-1} + q_{|X|-1}} & \frac{q_{|X|-1} q_{|X|-1}}{q_{|X|-1} + q_{|X|-1}}
\end{bmatrix}.
\]

In this case, the only non-zero off-diagonal elements $k_{x,x'}(q)$ are negative elements when $x'$ directly follows $x$ in the ordering of states (or vice versa). This form of matrix $k(q)$ implies that an information structure is costly only to the extent that there are pairs of “neighboring” states $x,x'$ for which the distribution of signals conditional on those states are different. This information cost matrix function is closely related to the neighborhood-based cost functions we introduce in Section 4.
Example. Continuing the example of a buyer considering a security, if $k(q)$ is the “neighborhood-based” function described in equation (5) above, the buyer finds discriminating between adjacent asset values costly, and the total information cost depends on how rapidly the signals the buyer receives change as a function of the asset value.

Aside from its a priori appeal, this alternative information-cost matrix function has different implications for the behavior of the DM, which we describe in the next section.

For a large class of information-cost matrix functions $k(q_t)$, including both of these examples, we can solve the continuous time sequence problem described in this section, and show that the solution is equivalent to a certain static rational inattention problem. We present these results in the next section. The remainder of this section briefly discusses an additional restriction on the functions $k(q)$, the importance of linear time costs as opposed to exponential discounting, and our assumption that beliefs follow a diffusion process.

In Hébert and Woodford (2018), we derive this model from more primitive considerations, and our derivation shows that there exists a positive constant $m$ such that $k(q) - mg^+(q)$ is positive semi-definite.\footnote{The example in (5) does not satisfy this for any $m > 0$, but is the limit of a sequence that does.}

We also derive a more general continuous time problem, involving a controlled jump-diffusion process for beliefs, that features both exponential (standard) discounting and linear time costs. The model presented in this paper corresponds to a special case, in which only linear time costs are present and the information cost technology exhibits what we call a “preference for gradual learning.” Under these assumptions, it is always weakly optimal for the DM to choose not to have jumps in her beliefs, meaning that her beliefs will follow a pure diffusion process. No-discounting generates a great deal of tractability (and decision times are often short relative to the rate of time preference), and this “preference for gradual learning” allows us to focus on models that are closely related to existing models in psychology, neuroscience, and economics.
Other authors (e.g. Che and Mierendorff (2017), Zhong (2018)) have explored models in which beliefs are assumed to follow a jump process. In Hébert and Woodford (2018), we discuss conditions under which beliefs will follow a diffusion-like or jump-like process, with and without exponential discounting, and how our results relate to those papers. For robustness, in this paper, we show in Appendix Section C.1 that our equivalence result (Theorem 1 below) can be derived from an alternative model in which beliefs follow a pure jump process. Our subsequent results depend only on this theorem and thus are relevant to both diffusion-based and jump-based models. To preserve this robustness, we do not discuss topics like stopping times, which likely differ between diffusion-based and jump-based models, even when those models are both equivalent to the same static model.

3 Static and Dynamic Rational Inattention Problems

In most theories of rational inattention, including the classic formulations of Sims, only a single signal is collected for each decision that must be made. In a decision problem where an action is chosen once from a set of possibilities, the rational inattention problem is static; a signal is obtained (once) that depends on the state, an action is taken that depends on the signal, and that is all. The kind of dynamic optimization model proposed in the previous section seems quite different. Nonetheless, we establish below that in a broad class of cases, there is an equivalence between the information that is ultimately acquired in the dynamic model of the previous section and the information acquired in a static model of rational inattention, with a particular type of cost function. Thus, our dynamic model does not necessarily have different implications, on some dimensions, than a static rational inattention model; however, the dynamic optimization problem can provide a reason for interest in static information-cost functions of particular types.

We begin by explaining the form of a static rational inattention problem, and then de-
scribe our equivalence result. After introducing our equivalent result, we will discuss comparative statics, and relate those comparative statics to the information cost matrix function introduced in the previous section.

3.1 Static Models of Rational Inattention

Much of the notation from the previous section carries over to static models. We continue to use \( x \in X \) as the underlying state of nature, and \( u_{a,x} \) as the payoff from taking action \( a \in A \) in state \( x \). We continue to define \( \hat{u}(q) \) as the payoff from taking the optimal action with beliefs \( q \), and let \( q_0 \) denote the DM’s initial beliefs, prior to gathering information.

In static rational inattention models, the DM chooses a “signal structure,” consisting of a signal alphabet \( S \) (a finite set) and a conditional probability, for each state \( x \), of each signal, \( p = \{ p_s \in \mathcal{P}(S) \}_{x \in X} \). The signal structure \( p \) generates, under the prior beliefs \( q_0 \), an unconditional probability of each signal, \( \pi_s(p, q_0) \). After receiving a signal \( s \in S \), the DM will hold beliefs \( q_s(p, q_0) \), defined by Bayes’ rule. Let \( C(p, q_0; S) : \mathcal{P}(S)^{|X|} \times \mathcal{P}(X) \to \mathbb{R} \) be the cost of choosing a signal structure \( p \) and alphabet \( S \), given initial prior \( q_0 \). The standard static rational inattention problem, given the signal alphabet \( S \),

\[
\max_{\{p_s \in \mathcal{P}(S)\}_{x \in X, s \in S}} \sum_{s \in S} \pi_s(p, q_0)\hat{u}(q_s(p, q_0)) - \theta C(p, q_0; S),
\]

where \( \theta > 0 \) is a multiplicative factor that parameterizes the cost of information. Note that the problem can be rewritten as a choice of the signal probabilities \( \pi_s \) and posteriors \( q_s \), instead of the signal structure \( p \); for any \( \pi_s \) and \( q_s \) such that \( \sum_{s \in S} \pi_s q_s = q_0 \), there is a unique signal structure \( p \) such that \( \pi_s = \pi_s(p, q_0) \) and \( q_s = q_s(p, q_0) \).

In the classic formulation of Sims, a problem of the form of (6) is considered, in which

\[14\] The full problem includes a choice over the signal alphabet \( S \). A standard result, which will hold for all of the cost functions we study, is that \( |S| = |A| \) is sufficient.
the cost function \( C(p, q; S) \) is given by the mutual information between the signal and the state. Mutual information can be defined using Shannon’s entropy,

\[
H_{\text{Shannon}}(q) = -\sum_{x \in X} (e^T \mathbf{x} q) \ln(e^T \mathbf{x} q),
\]

where \( e_x \in \mathbb{R}^X \) is the vector with a one corresponding to state \( x \), and zeros elsewhere.

Shannon’s entropy can be used to define a measure of the degree to which each posterior \( q_s \) differs from the prior \( q_0 \), the Kullback-Leibler (KL) divergence,

\[
D_{\text{KL}}(q_s || q_0) = H_{\text{Shannon}}(q_0) - H_{\text{Shannon}}(q_s) + (q_s - q_0)^T H_{q_s}^{\text{Shannon}}(q_0).
\]

Mutual information is the expected value of the KL divergence over possible signals,

\[
I_{\text{Shannon}}(p, q_0; S) = \sum_{s \in S} \pi_s(p, q_0) D_{\text{KL}}(q_s(p, q_0) || q_0).
\]

It is a measure of the informativeness of the signal structure \( p \), in that it provides a measure of the degree to which the signal changes what one should believe about the state, on average. Mutual information is not, however, the only possible measure of the informativeness of an information structure, or the only plausible cost function for a static rational inattention problem. We introduce alternatives in the next section, but first return to our discussion of the continuous-time problem introduced in Section 2.

### 3.2 The Equivalence of Static and Dynamic Models

To prove our equivalence result, we restrict our attention to information-cost matrix functions that are “integrable,” in the sense described by the following assumption.

**Assumption 1.** There exists a twice-differentiable function \( H : \mathbb{R}_{+}^{|X|} \rightarrow \mathbb{R} \) such that, for all
In the interior of the simplex,

$$\text{Diag}(q_t)^{-1}k(q_t)\text{Diag}(q_t)^{-1} = H_{qq}(q_t).$$

(10)

This class includes a number of information-cost matrix functions of interest: for example, it includes the case in which $k(q_t)$ is the inverse Fisher information matrix, which we will show corresponds to the standard rational inattention model, and the case in which $k(q_t)$ is the “neighborhood-based” function that we introduce in section 4. It is, however, more restrictive than the class of information-cost matrix functions defined in Section 2.\textsuperscript{15} We shall refer to the function $H$ as the “entropy function,” for reasons that will become clear below. Note that $H(q)$ is convex, by the positive semi-definiteness of $k(q)$, and homogenous of degree one ($q^T \cdot H_{qq}(q) = t^T k(q) \text{Diag}(q)^{-1} = \vec{0}$).

For every convex function $H$, there is a “Bregman divergence,”

$$D_H(q_s||q) = H(q_s) - H(q) - (q_s - q)^T H q(q).$$

(11)

The Kullback-Leibler divergence, for example, is a Bregman divergence (see (8)), with an entropy function equal to the negative of Shannon’s entropy.

To analyze our continuous time problem, we begin by proving that the information constraint (2) binds. Because the constraint binds, we can substitute the constraint into the HJB equation (3), and obtain the following result:

**Lemma 1.** Anywhere the value function $V(q_t)$ is twice-differentiable and the DM chooses not to stop, for all $\sigma \in M(q_t),$

$$tr[\sigma^T \{\text{Diag}(q_t)V_{qq}(q_t)\text{Diag}(q_t) - \theta k(q_t)\} \sigma] \leq 0,$$

(12)

\textsuperscript{15}It rules out, e.g., constant $k(q)$ (a hypothetical $H$ would have asymmetric third-derivative cross-partials).
where $\theta = \chi^{-1} \kappa$, with equality under the optimal policy.

Proof. See the Appendix, Section B.1.

The parameter $\theta$, introduced in the lemma, describes the race between information acquisition and time in this model. The larger the penalty for delay, and the tighter the information constraint, the larger the parameter $\theta$. We now describe our equivalence result, and then outline the key step of its proof, which relies on this lemma.

**Theorem 1.** Under Assumption 1, the value function that solves the continuous time sequential evidence accumulation problem is

$$V(q_0) = \max_{\pi \in \mathcal{P}(A), \{q_a \in \mathcal{P}(X)\}_{a \in A}} \sum_{a \in A} \pi(a)(u_a^T \cdot q_a) - \theta \sum_{a \in A} \pi(a)D_H(q_a || q_0),$$

subject to the constraint that $\sum_{a \in A} \pi(a)q_a = q_0$, where $D_H$ is the Bregman divergence associated with the entropy function $H$ that is defined by Assumption 1.

There exist maximizers $\pi^*$ and $q_a^*$ such that $\pi^*$ is the unconditional probability, in the continuous time problem, of choosing a particular action, and $q_a^*$, for all $a$ such that $\pi^*(a) > 0$, is the unique belief the DM will hold when stopping and choosing that action.

Proof. See the Appendix, Section section B.2.

The continuous time sequential evidence accumulation problem is equivalent to a static rational inattention problem, with a particular kind of static information-cost function,

$$C(p, q_0; S) = \sum_{s \in S} \pi_s(p, q_0)D_H(q_s(p, q_0) || q_0),$$

with the signal space $S$ identified with the set of possible actions $A$. Following Caplin et al. (2018b), we call such a cost function “uniformly posterior-separable.”

18
The mutual information cost function (9) proposed by Sims is one such cost function. In this case, the entropy function $H$ is the negative of Shannon’s entropy (7), the corresponding information-cost matrix function is the inverse Fisher information matrix (4), the Bregman divergence is the Kullback-Leibler divergence (8), and the information measure defined by (13) is mutual information (9). Thus Theorem 1 provides a foundation for the standard static rational inattention model, and hence for the same predictions regarding stochastic choice as are obtained by Matějka et al. (2015).

On the other hand, Theorem 1 also implies that other cost functions can also be justified. Indeed, any (twice-differentiable) uniformly posterior-separable cost function (13) can be given such a justification, by choosing the information cost matrix function defined by equation (10). However, not all information cost matrix functions are reasonable. As discussed in the previous section, the information cost matrix function describes how hard it is to distinguish any pair of states. In many economic applications, there is a natural ordering or structure of the states, and we would like the information cost matrix function and the associated entropy function and Bregman divergence to reflect this structure. In the next section, we propose such a cost function.

First, however, we outline the key step of our proof, and then illustrate the important role that the information cost matrix function plays in comparative statics for the DM’s choices. Our proof strategy is best described as “guess and verify,” in that we start with the static value function described in Theorem 1 and then show that it is the value function of the continuous time model described in Section 2. The key step of the proof is to show that the static value function satisfies (12) in Lemma 1.\footnote{Technical footnote: the “anywhere the value function is twice differentiable” caveat of Lemma 1 is relevant for our problem. The PDE described by equation (12) is “degenerate elliptic” and hence will not in general have a classical solution. Indeed, we do not prove that our static value function is twice differentiable everywhere, and suspect it is not at points where the “consideration set” (the set of actions with $\pi(a) > 0$, Caplin et al. (2018a)) changes. In our proof, we establish that the static problem value function is convex and continuously differentiable, which is sufficient to invoke a generalized version of Ito’s lemma for convex functions to verify that the static value function is the solution to the continuous time problem.} For expositional purposes, we will
assume that the optimal policies of the static model, \( \pi^* (a; q_0) \) and \( q^*_a (q_0) \), are differentiable with respect to \( q_0 \) and strictly interior (we do not require these assumptions in the proof).

We begin by examining the first-order conditions with respect to \( q_0 \) and applying the envelope theorem. Let \( \kappa (q_0) \) denote the vector of multipliers on the constraint that \( \sum_{a \in A} \pi (a) q_a = q_0 \). We have

\[
\text{FOC: } u_a - \kappa (q_0) - \theta H_q (q^*_a (q_0)) + \theta H_q (q_0) = 0, \forall a \in A, \tag{14}\]

\[
\text{ET: } V_q (q_0) = \kappa (q_0) + \sum_{a \in A} \pi^* (a; q_0) (q^*_a (q_0) - q_0)^T \cdot H_{qq} (q_0) = \kappa (q_0). \tag{15}\]

Now consider a perturbation \( q_0 \rightarrow q_0 + \varepsilon z \), for some tangent vector \( z \). Combining the FOC and ET, and then differentiating with respect to \( \varepsilon \) and evaluating at \( \varepsilon = 0 \),

\[
V_{qq} (q_0) \cdot z = \theta H_{qq} (q_0) \cdot z - \theta H_{qq} (q^*_a (q_0)) \cdot \frac{dq^*_a (q_0 + \varepsilon z)}{d \varepsilon} \big|_{\varepsilon = 0}, \forall a \in A. \tag{15}\]

Observe that, due to the constraint, \( \sum_{a \in A} \frac{d (\pi^* (a; q_0 + \varepsilon z) q^*_a (q_0 + \varepsilon z))}{d \varepsilon} \big|_{\varepsilon = 0} = z \). Multiplying both sides of equation (15) by \( \frac{d (\pi^* (a; q_0 + \varepsilon z) q^*_a (q_0 + \varepsilon z)^T)}{d \varepsilon} \big|_{\varepsilon = 0} \), and then taking sums,

\[
z^T \cdot V_{qq} (q_0) \cdot z = \theta z^T \cdot H_{qq} (q_0) \cdot z - \theta \sum_{a \in A} \pi^* (a; q_0) \left( \frac{dq^*_a (q_0 + \varepsilon z)}{d \varepsilon} \big|_{\varepsilon = 0} \right)^T \cdot H_{qq} (q^*_a (q_0)) \cdot \frac{dq^*_a (q_0 + \varepsilon z)}{d \varepsilon} \big|_{\varepsilon = 0}
- \theta \sum_{a \in A} \frac{d \pi^* (a; q_0 + \varepsilon z)}{d \varepsilon} \big|_{\varepsilon = 0} q^*_a (q_0)^T \cdot H_{qq} (q^*_a (q_0)) \cdot \frac{dq^*_a (q_0 + \varepsilon z)}{d \varepsilon} \big|_{\varepsilon = 0}. \]

By Assumption 1, \( q^T \cdot H_{qq} (q) = 0 \), and hence the last line in this expression is zero. By the convexity of \( H \), the summation on the second line is positive. Therefore, by Assumption 1,

\[
z^T \cdot V_{qq} (q_0) \cdot z \leq z^T \cdot \text{Diag} (q_0)^{-1} k (q_0) \text{Diag} (q_0)^{-1} \cdot z, \]

20
establishing that (12) holds. To show that there is a direction $z^*$ in which (12) holds with equality, it is sufficient to show that $\frac{dq^*_a(q_0+\varepsilon z^*)}{d\varepsilon}|_{\varepsilon=0} = 0$ for all $a \in A$. In any direction $z$ spanned by the initial $q^*_a(q_0) - q_0$, it is not optimal for the DM to change the $q^*_a(q_0)$, only the probabilities $\pi^*(a,q_0)$ (this property, “Locally Invariant Posteriors,” was shown by Caplin et al. (2018b)). Thus, any of these directions can serve as $z^*$.

3.3 Comparative Statics

Any uniformly posterior-separable cost function can be justified by some information cost matrix function. In this subsection, we ask whether the cost function matters in terms of the DM’s observable behavior. In some sense, the recoverability result of Caplin et al. (2018b) shows that the answer must be “yes”– if the cost function can be uniquely recovered from data on the likelihood of the DM’s action in each state, then that likelihood must be influenced by the cost function. Our particular point is to relate the comparative statics of the DM’s posteriors with respect to payoffs to the information cost matrix function.

To illustrate this point, we return to our running example of a buyer considering purchasing a security. The comparative statics of this case are particularly transparent, because there are only two actions, $A = \{L, R\}$; similar but more complicated formulas can be obtained in the many-action case. Combining the first-order conditions (14) for the two actions, and using the homogeneity of degree zero of $H_q(\cdot)$ (which follows from the homogeneity of degree one of $H$), we find that, continuing to assume interior solutions,

$$s - Kt = \theta H_q(\pi^*_L q^*_L) - \theta H_q(q_0 - \pi^*_L q^*_L).$$

Now consider a perturbation of the security payoff for a particular asset value $x \in X$, $s(\varepsilon) = (...)$. 

---

17That any such direction can serve as $z^*$ indicates that there are (usually) many optimal policies in the continuous time problem that achieve the same value function. Intuitively, at each point, if the DM does not learn in some particular direction, she could always learn in that direction in the next instant.
s + \varepsilon e_x$, and its effect on the probability of accepting the security conditional on some other $x' \in X$. Assuming that $q_L^* \neq q_0$, meaning that the buyer gathers some information,\(^{18}\) we can differentiate the above first-order equation and derive the comparative static

$$
\frac{d(\pi^*_L(e) e^T_x q^*_L(e))}{d\varepsilon} |_{\varepsilon=0} = e^T_x \theta H_{qq}(\pi^*_L q^*_L) + \theta H_{qq}(q_0 - \pi^*_L q^*_L)]^{-1} e_x.
$$

(16)

For this two-action model, this can be viewed as a definition of whether learning about the states $x$ and $x'$ are complements or substitutes (note that it is symmetric). If the reward for acceptance in state $x$ increases, and learning about states $x$ and $x'$ are complements, the DM will endogenously choose to accept more often in state $x'$. By Assumption 1, the Hessians $H_{qq}(q)$ are transformed versions of the information cost matrix function $k(q)$. Intuitively, the difficulty of discriminating between the states $x$ and $x'$, $-k_{xx'}(q)$, is closely related to whether or not they are complements or substitutes with respect to learning.

To understand the role of the matrix inverse, decompose the matrix $H_{qq}(\pi^*_L q^*_L) + H_{qq}(q_0 - \pi^*_L q^*_L)$ into a diagonal matrix $H_{diag}(\pi_L q_L)$ and the negative of an off-diagonal matrix $H_{off}(\pi_L q_L)$,

$$
H_{qq}(\pi^*_L q^*_L) + H_{qq}(q_0 - \pi^*_L q^*_L) = H_{diag} - H_{off}.
$$

Note that $H_{diag}$ has entirely positive entries, and that the off-diagonal entries $H_{off}$ are scaled versions of the off-diagonal entries of $k(q)$. We can write, ignoring the issue of whether the infinite sum converges,

$$
[\theta H_{qq}(\pi^*_L q^*_L) + \theta H_{qq}(q_0 - \pi^*_L q^*_L)]^{-1} = \theta^{-1} H_{diag}^{-1} \sum_{j=0}^{\infty} (H_{diag}^{-1} H_{off})^j.
$$

We can think of our comparative static (16) as consisting a sequence of “rounds” of effects. The “zero-round” effect is to increase the likelihood of the state $x$ whose payoff has

\(^{18}\)This condition ensures that $H_{qq}(\pi_L q_L) + H_{qq}(q_0 - \pi_L q_L)$ is positive-definite.
increased. The “first-round” effect is governed by the difficulty of discriminating between \( x \) and \( x' \). If it is difficult to discriminate between \( x \) and \( x' \), but easy to discriminate between \( x \) and \( x'' \), the DM will want to make acceptance relatively more likely conditional on \( x' \). However, this involves discriminating between \( x' \) and \( x'' \), and hence leads to a “second-round” effect. Third- and higher-round effects can be defined in similar fashion. With the inverse Fisher information matrix as the cost function, these rounds of effects are a function only of \( \pi_L q_L \) and \( q_0 \) and hence are identical for pairs \((x, x')\) and \((\bar{x}, \bar{x}')\) with identical probabilities under \( q_L \) and \( q_0 \). With the example neighborhood-based information cost matrix function (5), first-round effects occur only between adjacent states, second round effects only between states that are “two spaces apart,” and so on.

At this point, we have shown that any uniformly posterior-separable cost function can be justified by our continuous time framework, with some information cost matrix function, that the information cost matrix function describes the difficulty or ease with which the DM can discern certain states, and that this difficulty or ease matters for behavior. Given these results, our next section proposes a specific class of information cost matrix functions, and hence uniformly posterior-separable cost functions, that we will argue are superior in certain respects to the standard mutual information cost function.

### 4 Neighborhood-Based Cost Functions

We begin by introducing a structure on the state space, to capture the idea that some pairs of states are harder to discern than others. Using this structure, we describe an information cost matrix function and the associated uniformly posterior-separable cost function.
4.1 The Neighborhood Framework

Suppose that the state space $X$ can be written as the union of a finite collection of “neighborhoods” $\{X_i\}$, and let $\mathcal{I}$ denote the set of these neighborhoods. Suppose furthermore that the state space is connected, in the sense that any two states can be connected by a sequence of overlapping neighborhoods.\textsuperscript{19} Define the selection matrices $E_i$ as the $|X_i| \times |X|$ matrices that select each of the elements of $X_i$ from a vector of length $|X|$.

For any belief $q \in \mathcal{P}(X)$, let $\bar{q}_i \equiv \sum_{x \in X_i} e_i^T q$ be the prior probability that some state belonging to neighborhood $X_i$ occurs. Let $q_i \in \mathcal{P}(X_i)$ be the conditional probability distribution over states in neighborhood $X_i$, given the belief $q$ and conditional on the state being in neighborhood $X_i$. That is, for all $x \in X_i$, $q_i \equiv \frac{1}{\bar{q}_i} E_i q$. The information cost matrix function has a neighborhood structure if, for all $q$ in the interior of the simplex,

$$k_N(q; \rho) = \begin{cases} \sum_{i \in \mathcal{I}} c_i \bar{q}_i |X_i|^{-\rho} E_i (g^+(q_i))^{2-\rho} E_i & \rho \neq 2, \\ \sum_{i \in \mathcal{I}} c_i \bar{q}_i |X_i|^{-1} E_i (I - q_i t^T) (I - t q_i^T) E_i & \rho = 2. \end{cases}$$

where $g^+(\cdot)$ is the inverse Fisher information matrix, $\rho \geq 1$ is a constant, and the constants $c_i$ are strictly positive for each $i \in \mathcal{I}$. Within each neighborhood, we have assumed that the cost of information is proportional to the inverse Fisher information to some power, to retain to some of the tractability of the original rational inattention model. However, by varying the neighborhood structure, we can impose a variety of assumptions about how difficult it is to discriminate between various states. In the special case in which there is only a single neighborhood and $\rho = 1$, $k_N$ is simply the inverse Fisher information matrix.

We should emphasize that using the inverse Fisher information matrix to some power within each neighborhood is useful from a tractability perspective, but is in no way essential.

\textsuperscript{19}That is, for any two states $x, x' \in X$, there exists a sequence of states $\{x_0, \ldots, x_n\}$ with $x_0 = x, x_n = x'$, and the property that for any $1 \leq m \leq n$, states $x_m$ and $x_{m-1}$ belong to a common neighborhood.
to the idea of using neighborhoods. One could use a neighborhood structure with almost any “neighborhood” information cost matrix function. Our introduction of the exponent \( \rho \) (as opposed to simply using \( \rho = 1 \)) follows Dean and Neligh (2018), who provide experimental evidence consistent with a neighborhood information structure, but find that values of \( \rho \) substantially larger than one provide the best fit to their experimental data. More generally, there is no reason aside from parsimony to assume that the same “neighborhood” information cost matrix function applies within each neighborhood.

We can use the information-cost matrix function in our continuous-time problem (the problem defined in Section 2).\(^{20}\) It satisfies the Assumption 1, and hence Theorem 1 applies. That is, there is an entropy function \( H_N(q) \) that can be used to define the static rational-inattention problem which is equivalent to the solution to the dynamic model.

**Lemma 2.** Let \( H_{\text{Gen}}^\text{Gen}(q_i; \rho) \) be the generalized entropy index of Shorrocks (1980) on the neighborhood \( i \in I \), defined for any interior \( q_i \) as

\[
H_{\text{Gen}}^\text{Gen}(q_i; \rho) = \begin{cases}
\frac{1}{|X_i|} \left( \frac{1}{(p-2)(p-1)} \sum_{x \in X_i} \{(|X_i|e_x^T q_i)^{2-p} - 1\} \right) & \rho \notin \{1, 2\} \\
-\frac{1}{|X_i|} \sum_{x \in X_i} \ln(e_x^T q_i) & \rho = 2 \\
\sum_{x \in X_i} e_x^T q_i \ln(e_x^T q_i) & \rho = 1.
\end{cases}
\]

The entropy function \( H_N(q; \rho) \) associated with the neighborhood-based information-cost matrix function \( k_N(q; \rho) \) is, for any \( q \) in the relative interior of the simplex,

\[
H_N(q; \rho) = -\sum_{i \in I} c_i \bar{q}_i H_{\text{Gen}}^\text{Gen}(q_i; \rho),
\]

and is defined on the boundary by continuity for \( \rho < 2 \) and as infinity for \( \rho \geq 2 \).

\(^{20}\)Our derivation of the continuous-time model (Hébert and Woodford (2018)) requires that \( k_N(q) - mg^+(q) \geq 0 \) for some strictly positive constant \( m \). We can satisfy this requirement by including a neighborhood containing all states, with an arbitrarily small constant \( c_i \) associated with that neighborhood.
The special case of \( \rho = 1 \) corresponds to (the negative of) Shannon’s entropy within each neighborhood. The exponent \( \rho \) controls the curvature of the entropy function (Dean and Neligh (2018) use the following analogy: \( H^{\text{Gen}}(q; \rho) \) is to Shannon’s entropy as CRRA utility is to log utility). Using the our generalized entropy function \( H_N(q; \rho) \), we can define a Bregman divergence, \( D_N(q||q; \rho) \), as in (11), and a static rational inattention problem\(^{21}\) (as in Theorem 1).

\[
V_N(q) = \max_{\pi \in \mathcal{P}(A), \{q_a \in \mathcal{P}(X)\}_{a \in A}} \sum_{a \in A} \pi(a)(u_a^T \cdot q_a) - \theta \sum_{a \in A} \pi(a) D_N(q_a||q; \rho). \tag{17}
\]

It is sometimes more convenient to work with cost functions defined over signals \( \{p_x \in \mathcal{P}(S)\}_{x \in X} \), as opposed to posteriors \( q_a \) and unconditional probabilities \( \pi \) (e.g. (6)). Below we rewrite the problem with a neighborhood cost function in this form, using Bayes’ rule.

**Lemma 3.** The static rational inattention problem in (17) can be written as

\[
V_N(q) = \max_{\{p_x \in \mathcal{P}(S)\}_{x \in X}} \sum_{x \in S} \pi_s(p, q_0) \hat{u}(q_s(p, q_0)) \]

\[
- \theta \sum_{i \in \mathcal{I}} c_i |X_i|^{1-p} q_i^{p-1} \sum_{x \in X_i} (e_x^T q_i)^{2-p} D_\rho(p_x||pE_i^T q_i),
\]

where

\[
D_\rho(p_x||\pi) = \begin{cases} 
\frac{1}{(\rho-2)(\rho-1)} \sum_{s \in S: \pi_s > 0} \pi_s ((\frac{p_{xs}}{\pi_s})^{2-\rho} - 1) & \rho \neq \{1, 2\} \\
\sum_{s \in S: \pi_s > 0} \pi_s \ln(\frac{\pi_s}{p_{xs}}) & \rho = 2 \\
\sum_{s \in S: \pi_s > 0} p_{xs} \ln(\frac{p_{xs}}{\pi_s}) & \rho = 1.
\end{cases}
\]

**Proof.** See the Appendix, Section B.4. \(\square\)

The divergences \( D_\rho \) are known as the \( \alpha \)-divergences (under a different parameterization)\(^{21}\) To deal with the boundaries in the \( \rho \geq 2 \) case, we assume \( q \) has full support in this problem.

---

\(^{21}\)To deal with the boundaries in the \( \rho \geq 2 \) case, we assume \( q \) has full support in this problem.
and are a transformed version of the Renyi divergences (Amari and Nagaoka (2007)). In the special case of \( \rho = 1 \), \( D_\rho \) is the Kullback-Leibler divergence. If \( \rho = 1 \) and there is only a single neighborhood, this is the standard rational inattention problem. The relevance of alternative neighborhood structures is illustrated by the following observation.

**Corollary 1.** Consider a rational inattention problem with a neighborhood-based information-cost function (Lemma 3), and let \( x, x' \) be two states with the property that (i) \( u_{a,x} = u_{a,x'} \) for all actions \( a \in A \), (ii) \( q_x = q_{x'} \), and (iii) the set of neighborhoods \( \{X_i\} \) such that \( x \in X_i \) is the same as the set such that \( x' \in X_i \). Then under the optimal policy, \( p^*_x = p^*_{x'} \). If \( \rho = 1 \), this result holds even if \( q_x \neq q_{x'} \).

*Proof.* The result follows directly from the problem in Lemma 3. \( \square \)

The significance of Corollary 1 can be seen if we consider the predictions of rational inattention for a standard form of perceptual discrimination experiment, an application we describe in the next section. In these experiments, payments are based on correct and incorrect responses. As a result, two states in which the correct response and ex-ante likelihoods are identical will (for a single-neighborhood cost function) have the same likelihood of a correct response. Experimental evidence (intuitively) shows that in some states it is more difficult to determine the correct response than in other states.

### 4.2 A Specific Proposal: The Fisher Information Cost Function

Our neighborhood-based framework is flexible enough to accommodate a wide range of structures on the state space. However, in practice, we believe there is a particular structure that it relevant in many settings: when the states can be ordered on a line. Suppose there are \( M + 1 \) ordered states, \( X^M = \{0, 1, \ldots, M\} \), and that each pair of adjacent states forms a neighborhood, \( X_i = \{i, i+1\} \), for all \( i \in \{0, 1, \ldots, M-1\} \). Thus two states belong to a common neighborhood if and only if one comes immediately after the other in the sequence.
This captures the idea that the available measurement technologies all respond similarly in states that are “similar,” in the sense of being at nearby positions in the sequence, so that repeated measurements are necessary to reliably distinguish between two states if and only if they are near each other in the sequence. Suppose further that \( c_i = 1 \) for all \( i \), implying that it is equally difficult to distinguish two neighboring states at all points in the sequence.\(^{22}\)

Under these assumptions, for any \( q \) with full support,

\[
H_N(q; \rho, M) = \frac{1}{\rho - 2} \left( \frac{1}{\rho - 1} \sum_{j=0}^{M-1} \left( \frac{1}{2} (e_j^T + e_{j+1}^T) q \right) \times \right.
\]
\[
\left\{ \left( \frac{e_j^T q}{\frac{1}{2} (e_j^T + e_{j+1}^T) q} \right)^{2-\rho} + \left( \frac{e_{j+1}^T q}{\frac{1}{2} (e_j^T + e_{j+1}^T) q} \right)^{2-\rho} - 2 \right\}. \tag{18}
\]

Defining the function \( g(x; \rho) = \frac{1}{\rho - 2} \frac{1}{\rho - 1} x^{2-\rho} \), we can rewrite this expression as

\[
H_N(q; \rho, M) = \sum_{j=0}^{M-1} \frac{1}{2} (e_j^T + e_{j+1}^T) q) \{ g(1 - \frac{1}{2} (e_{j+1}^T - e_j^T) q; \rho) + g(1 + \frac{1}{2} (e_{j+1}^T - e_j^T) q; \rho) - 2 g(1; \rho) \}.
\]

This function penalizes differences in the function \( g(\cdot; \rho) \) between states \( i \) and \( i + 1 \) and their average. Because the \( g(\cdot; \rho) \) function is convex, any changes in probability are penalized. As a result, it will be optimal in the static rational inattention problem for the DM to smooth posterior probabilities across states of the world.

If \( q_i \) and \( q_{i+1} \) are close to each other for all \( i \), a second-order Taylor approximation of the function \( g(u; \rho) \) around \( u = 1 \) clarifies this point:

\[
H_N(q; \rho, M) \approx \frac{1}{4} \sum_{j=0}^{M-1} \frac{(e_{j+1}^T - e_j^T) q)^2}{\frac{1}{2} (e_j^T + e_{j+1}^T) q}. \tag{19}
\]

Note that this approximation is exact in the \( \rho = 0 \) case, and that the approximation is the

\(^{22}\)If \( c_i \) is the same for all \( i \), we can without loss of generality set it equal to one, as the multiplier \( \theta \) can still be used to scale the overall magnitude of information costs.
same for all values of $\rho$. Intuitively, all of the $H^{Gen}(q_i; \rho)$ resemble each other in the neighborhood of the uniform distribution, and hence when applied to a neighborhood with two states with similar probabilities are approximately identical.

For many applications, it is more convenient to work with a continuous state space. Based on this approximation result, it is tempting to infer that, in the limit as the number of states $M \to \infty$, if the discrete distributions $q_M$ converge to differentiable function $q$,

$$
\lim_{M \to \infty} H_N(q_M; \rho, M) = \frac{1}{4} \int_{\text{supp}(q)} \frac{(q'(x))^2}{q(x)} dx,
$$

where $\text{supp}(q)$ denotes the support of $q$. From this, we define a continuous state rational inattention problem:

$$
V_N(q) = \sup_{\pi \in \mathcal{P}(A), \{q_a \in \mathcal{P}_{LipG}\}_{a \in A}} \sum_{a \in A} \pi(a) \int_{\text{supp}(q)} u_a(x) q_a(x) dx - \frac{\theta}{4} \sum_{a \in A} \left\{ \pi(a) \int_{\text{supp}(q)} \frac{(q'_a(x))^2}{q_a(x)} dx \right\} + \frac{\theta}{4} \int_{\text{supp}(q)} \frac{(q'(x))^2}{q(x)} dx,
$$

subject to the constraint that, for all $x$,

$$
\sum_{a \in A} \pi(a) q_a(x) = q(x).
$$

In this expression, $x$ is the exogenous state, $u_a(x)$ is the utility of action $a \in A$ in state $x$, $q(x)$ is the prior over the states, and $q_a(x)$ is the posterior belief conditional on taking action $a$.

This problem has an alternative formulation as a choice of signal structure:

$$
V_N(q) = \sup_{\{p_a\}_{a \in A} \in \mathcal{P}_{LipG}(A)} \int_{\text{supp}(q)} q(x) \sum_{a \in A} p_a(x) u_a(x) dx - \frac{\theta}{4} \int_{\text{supp}(q)} q(x) \sum_{a \in A} \frac{(p'_a(x))^2}{p_a(x)} dx,
$$

where $\mathcal{P}_{LipG}(A)$ is the set of mappings $\{p_a : \text{supp}(q) \to \mathbb{R}^+\}_{a \in A}$ such that for each $x$,
\[ \sum_{a \in A} P_a(x) = 1, \] and for each action \( a \), the function \( p_a(x) \) is a differentiable function of \( x \) with a Lipschitz-continuous derivative.

This alternative formulation shows that our proposed static information-cost function is just the weighted (by \( q(x) \)) average of the Fisher information (Cover and Thomas (2012), sec. 11.10), a measure of the local discriminability of states.\(^{23}\) It is for this reason that we refer to our proposal as the “Fisher information cost function.” Like mutual information, the Fisher-information cost function is a single-parameter cost function, and it can also be applied in almost any context, as long as the state space is continuous. Unlike mutual information, the Fisher information depends on the topological structure of the state space.

We prove the convergence of the static problem described in Theorem 1 to this problem formally in the Technical Appendix, Section C.2, under some regularity assumptions on the prior \( q \) (differentiability, with a Lipschitz-continuous derivative, and support on a compact set), for the specific case of \( \rho = 1 \).\(^{24}\) In the proof, we show that the limiting optimal posteriors \( q_a \) are also differentiable and have the same support as \( q \) (so the Fisher information integrals make sense) and that their derivatives are also Lipschitz-continuous (which helps prove convergence). We refer to the set of full-support, differentiable probability distribution functions with Lipschitz-continuous derivatives as \( \mathcal{P}_{\text{LipG}} \). The proof is quite technical, and the relevant economics are summarized by the approximation (19).

We have proposed a neighborhood structure that captures the idea that states might be ordered on a line. We now turn to applications, to illustrate the effects of using our proposed alternative in the place of the standard rational inattention cost function.

---

\(^{23}\)The equivalence of the two formulations is shown in the Technical Appendix, section C.2, where we also provide further discussion of the connection with Fisher information.

\(^{24}\)We also assume bounded utilities. We think the result holds for other values of \( \rho \), and without some of our regularity assumptions, but generalizing our quite technical proof is difficult.
5 Applications of Neighborhood-Based Cost Functions

In this section, we apply our results to several applications of rational inattention. The first three applications concern binary choices, the fourth a linear-quadratic-Gaussian environment. These two environments cover a wide range of existing applications of rational inattention (for a survey, see Mackowiak et al. (2018)).

5.1 Security Design

In this application, we apply our framework to the mode of security design model with adverse selection in Yang (2017),\textsuperscript{25} which builds on the buyer’s decision problem that we have used as an example thus far. We will briefly summarize the environment, and encourage readers to refer to Yang (2017) for a richer exposition.

A seller offers a security $s \in \mathbb{R}_+^{|X|}$, whose payoffs are contingent on the realized value of the assets backing the security, $x \in X \subseteq \mathbb{R}_+$, to a buyer at a price $K$. The buyer’s problem (our example earlier in the paper) is to gather information about which asset values $x \in X$ are most likely and then accept (“like,” $L$) or reject ($R$) this take-it-or-leave it offer. Both parties are risk-neutral, and the seller discounts the cashflows by a factor $\beta < 1$, relative to the buyer. The security is constrained by limited liability, $0 \leq e^T x \leq x$.

The seller designs the security and offers a price, solving

$$\max_{s, K \geq 0} \pi_L(s, K) q_L(s, K)^T (Kt - \beta s).$$

subject to the limited liability constraint. In this expression, $\pi_L(s, K)$ and $q_L(x; s, K)$ are the optimal policies of the buyer who solves a rational inattention problem of the form of

\textsuperscript{25}Our neighborhood cost function could also be applied in the same fashion to the model of security design with moral hazard in attention described in the appendix of Hébert (2018).
Theorem 1, specialized to the case of two actions,

\[
V(q_0; s, K) = \max_{\pi_L \in [0,1], q_L, q_R \in \mathcal{P}(X)} \pi_L q_L^T (s - K t) \\
- \theta \pi_L D_H(q_L || q_0) - \theta (1 - \pi_L) D_H(q_R || q_0),
\]

subject to the constraint that \( \pi_L q_L + (1 - \pi_L) q_R = q_0 \).

Yang (2017) shows that, with the standard rational inattention cost function \((D_H)\) is the Kullback-Leibler divergence), the optimal security design is a debt contract, \( s(x) = \min\{v(x), \bar{v}\} \) for some positive constant \( \bar{v} \). The analysis involves two different cases, depending on whether the seller attempts to ensure acceptance with certainty \((\pi_L = 1)\) or not, but the form of the optimal security is the same in both cases. To simplify our exposition, we will focus on the case with some possibility of rejection \((\pi_L < 1)\), and discuss the case of acceptance with certainty in appendix section §C.3.

We explore, numerically, how the result of Yang (2017) changes with alternative \( H(\cdot) \) functions. We consider three alternatives, our neighborhood-based function \( H_N \) with our pairwise neighborhood structure (equation (18)), a generalized entropy index cost function (the neighborhood cost function with only one neighborhood), and a “weighted” Shannon’s entropy. Weighted Shannon’s entropy (see, e.g., Nawrocki and Harding (1986)) is

\[
H_w(q) = \sum_{x \in \mathcal{X}} (e^T x w)(e^T x q) \ln \left( \frac{e^T x q}{l^T q} \right),
\]

where \( w \) is a vector of weights. Constant weights correspond to Shannon’s entropy.

Summarizing our results, we replicate numerically the proof of Yang (2017) that, with mutual information, the optimal security design is always a debt. In contrast, for weighted mutual information and the generalized entropy index, the shape of the security design depends on the weights and the prior, respectively. The neighborhood cost function, on the
other hand, appears to always generate the same shape irrespective of the prior, a result we speculate could be proven analytically in the continuous-state version of the model.

Below, we describe our calculation procedure, and the parameters we use to generate figures 3 and 4. In general, our choice of parameters is guided by a desire to illustrate the differences between the cost functions, and to ensure that acceptance is not certain \((\pi_L < 1)\).

Our numerical calculation uses the “first-order approach,” solving

\[
\max_{s,K \geq 0, \pi_L \in [0,1], q_L \in \mathcal{P}(X)} \pi_L q_T^T (K \mathbf{1} - \beta \mathbf{s})
\]

subject to the buyer’s first order condition and that beliefs remain in the simplex,

\[
s - K\mathbf{1} + \theta H_q(q_0 - \pi_L q_L) = \theta H_q(\pi_L q_L),
\]
\[
e^T_x(q_0 - \pi_L q_L) \geq 0, \forall x \in X,
\]

and the limited liability constraints.\(^{26}\)

Combining the first-order conditions of this security design problem and the constraints,

\[
(1 - \beta)s^* = \theta H_q(q - \pi_L^* q_L^*) - \theta H_q(\pi_L^* q_L^*) + \theta [H_q(q - \pi_L^* q_L^*) + H_q(\pi_L^* q_L^*)](\beta \pi_L^* q_L^* - \lambda + \nu),
\]

where \(\lambda\) and \(\nu\) are the multipliers on the limited liability constraints. This illustrates that the optimal security design is determined by the entropy function, and hence the information cost matrix function, subject to the caveat that \(\pi_L^* q_L^*\) is endogenous.\(^{27}\)

Our numerical experiment uses an \(X\) with twenty-one states, with values of \(x\) evenly spaced from 0 to 10. We use a seller \(\beta\) of 0.5, and prior \(q\) that is an equal-weighted mixture

\(^{26}\)We conjecture, but have not proven, that the first-order approach is valid in this context.
\(^{27}\)Our discussion of comparative statics in section §3 anticipates this result.
of a uniform and binomial (21 outcomes of a 50-50 coin flip) distribution. We have chosen these parameters to help illustrate the differences between the cost functions.\footnote{In particular, the effects of weighted vs. standard Shannon’s entropy are proportional to $\ln(\beta)$, so we choose a value of $\beta$ significantly different from one. The differences between the generalized entropy index and Shannon’s entropy disappear with a uniform prior, so we use the binomial part of the prior to highlight those differences. At the same time, it is helpful for numerical purposes to ensure the prior is significantly different from zero in each state, which is why we have the uniform part of the prior.}

For the generalized entropy and neighborhood-based cost functions, we use $\rho = 13$. This value is close to the estimated parameter of Dean and Neligh (2018) for these two cost functions, although there is no particular reason to apply parameters estimated for perceptual experiments to security design. The various cost functions are not of the same “scale,” so the same values of $\theta$ do not necessarily result in the securities of the same scale. We have chosen $\theta = \frac{1}{2}$ for Shannon’s entropy, $\theta = 1$ for weighted Shannon’s entropy and the neighborhood cost function, and $\theta = \frac{1}{50}$ for the generalized entropy function, which results in securities that are of the same scale but distinct in our graphs.

For our weighted Shannon’s entropy, we use

$$w(x) = \frac{3}{2} + \frac{x}{10}.$$ 

This linear weight structure effectively assumes that it is more costly for the buyer to learn about good states than about bad states. We will see that this induces the seller to offer the buyer more in good states, and hence makes the buyer’s security more equity-like. The more general point, which we believe could be shown analytically, is that almost any security design could be reverse-engineered as optimal given some weight matrix. This reinforces the need to consider what kinds of information costs are reasonable.

Our numerical results are shown in figures 3 and 4. The first of these shows the optimal security designs, the second the optimal monotone (in $x$) security designs. Our numerical calculations recover the result of Yang (2017) for the case of Shannon’s entropy. They
also illustrate our point that, with upward-sloping weights, the result for weighted Shannon’s entropy is equity-like. The “inverse hump-shape” of the optimal security with the generalized entropy index cost function is caused by the “hump-shape” of the prior. \(^{29}\) The optimal securities for mutual information and weighted mutual information are monotone, and hence do not differ between the two graphs, whereas the optimal securities for the neighborhood based cost function and (imperceptibly) the generalized entropy index are non-monotone, and hence do differ. For weighted mutual information and the generalized entropy index, monotonicity or a lack thereof is not guaranteed, as the shape of the optimal security depends on the weights and prior, respectively.

Our results for the neighborhood cost function appear, regardless of parameters, to result in the same “debt-like,” but non-monotone, optimal security. This security is non-monotone and rapidly changing in one area. Rapid changes in security values would cause rapid changes in buyer behavior with Shannon’s entropy, and hence be sub-optimal, but this is not the case with neighborhood cost functions. As a result, it is possible for the optimal security to have rapid changes. However, when we restrict the security to be monotone, the optimal security is a debt, suggesting that the result of Yang (2017) is robust to using neighborhood cost functions (but not the other two alternatives) under this additional restriction. We conjecture that it is possible to prove the optimality of debt among monotone securities with a Fisher information cost, in the continuous state case.

Observant readers might notice a second feature of the optimal security for neighborhood-based cost functions: the “flat” part isn’t exactly flat. This feature arises from the “tri-diagonal” nature of the information cost matrix function \(k(q)\), which leads to a difference equation describing the optimal security. As the number of states increases, the “flat” part of the security becomes increasingly flat. In the continuous state case, the difference equation becomes a differential equation, and we conjecture that the flat part is truly flat.

\(^{29}\)With a uniform prior, the optimal security with the generalized entropy index cost is also a debt.
5.2 Psychometric Functions

In this application, we discuss our theory in the context of perceptual experiments (for example, Shadlen et al. (2007) or Dean and Neligh (2018)). Suppose that the different states \( X = \{0, 1, 2, \ldots, M\} \), where \( M \) is an odd integer, represent different stimuli that may be presented to the subject, and that the subject is asked to classify the stimulus that is presented as one of two types (\( L \) or \( R \)); \( R \) is the correct answer if and only if \( x > M/2 \). For example, the stimuli might be visual images with different orientations relative to the vertical, with increasing values of \( x \) corresponding to increasingly clockwise orientations; the subject is asked whether the image is tilted clockwise or counter-clockwise relative to the vertical. The subject’s goal is often simply to give as many correct responses as possible; hence we suppose that \( u_{x,a} = 1 \) if \( a = R \) and \( x > M/2 \) or if \( a = L \) and \( x < M/2 \), while \( u_{x,a} = 0 \) in all other cases. Each of the possible stimuli is presented with equal prior probability, and hence both responses have equal ex ante probability of being correct.

Both mutual information and generalizations based on the generalized entropy index correspond to a special case of a neighborhood-based cost function, in which all states belong to the unique neighborhood. Hence condition (iii) of Lemma 1 holds for any pair of states, and by assumption conditions (i) and (ii) hold as well. In the problem just posed, Lemma 1 implies that the probability of response \( R \) must be the same for all states \( x < M/2 \), and also the same (but higher) for all states \( x > M/2 \). Changing the severity of the information constraint changes the degree to which the probability of responding \( R \) is higher when \( x > M/2 \), but the response probabilities still will depend only on whether \( x \) is greater or less than \( M/2 \). This is illustrated in Appendix Figure 1, which plots the optimal response frequencies as a function of \( x \), for alternative values of the cost parameter \( \theta \), in a numerical example in which \( C \) is given by mutual information and \( M = 20 \).

Alternatively, consider a neighborhood-based cost function in which the neighborhoods
are given by \( X_i = \{ i, i+1 \} \) for \( i = 1, 2, \ldots, M - 1 \), and the constants \( c_i \) are equal to one for all neighborhoods, as in Section 4.2. Suppose further that \( \rho = 1 \) (noting that our approximation results suggest this choice does not matter very much). These assumptions suffice to completely determine a static information cost function (Lemma 2).

With this alternative neighborhood structure, Corollary 1 no longer requires that the response frequencies be identical for any two states. Moreover, because the cost function penalizes large differences in signal frequencies (and hence in response frequencies) in the case of neighboring states, in this case an optimal policy involves a gradual increase in the probability of response \( R \) as \( x \) increases, even though the payoffs associated with the different actions jump abruptly at a particular value of \( x \). This is illustrated in Appendix Figure 2, which again shows the optimal response frequencies as a function of \( x \), for alternative values of \( \theta \), in the case of the neighborhood cost function just described. The sigmoid functions predicted by rational inattention with this cost function — with the property that response frequencies differ only modestly from 50 percent when the stimuli are near the threshold of being correctly classified one way or the other, and yet approach zero or one in the case of stimuli that are sufficiently extreme — are characteristic of measured “psychometric functions” in perceptual experiments of this kind.\(^{30}\)

### 5.3 Global Games and The Fisher-Information Cost Function

The continuity of choice probabilities despite discrete changes in payoffs is also an important issue for the global games literature (Morris and Yang (2016)). This literature typically

\(^{30}\)For the general concept of a psychometric function, see, for example, Gabbiani and Cox (2010), chap. 25, especially Figures 25.1 and 25.2, and discussion on p. 360; or Gold and Heekeren (2014), p. 356. For an example of an empirical psychometric function for the kind of task discussed in the text (classification of the dominant direction of motion for a field of moving dots), see Shadlen et al. (2007), Figure 10.1A. Note not only that the curve is monotonically increasing, with many data points corresponding to different response probabilities between zero and one, but also that the subject’s reward function is clearly of the kind assumed in the text: only two possible reward levels (for correct vs. incorrect responses), with a discontinuous change in the reward where the sign of the “motion strength” changes from negative to positive.
assumes a continuum of states, so for this application we will discuss the continuous state limit described in (20). We will compare the Fisher information cost function we proposed in Section 4.2 with the more standard mutual information cost function.

This application is motivated by the work of Yang (2015) and Morris and Yang (2016), who study global games (e.g. Morris and Shin (1998)) with endogenous information acquisition. In the well-known analysis of Morris and Shin (1998), with exogenous private information, there is a unique equilibrium despite the incentives for coordination across DMs (subject to some caveats and details that are not relevant for our discussion). In contrast, Yang (2015) demonstrates that allowing for endogenous information acquisition, with mutual information as the information cost, restores a multiplicity of equilibria.

The key to Yang’s result is that DMs can tailor the signals they receive to sharply discriminate between nearby states of the world, as discussed in our previous example. As a result, they can all coordinate their decision (say, to invest or not) on a particular threshold, and there are many such thresholds that can represent equilibria if coordinated upon. But this result depends on the fact that the mutual-information cost function does not make it costly to have abrupt changes in signal probabilities as the state of the world changes continuously. Morris and Yang (2016) develop the complementary result, showing that even in the case of an endogenous information structure, if signal probabilities must vary continuously with the state, there is again a unique equilibrium.

Here we show that a neighborhood-based cost function can provide a justification for the kind of continuity condition that the result of Morris and Yang (2016) requires. Those authors study a global game with two possible actions, “invest” and “not-invest,” with equilibrium behavior characterized by a probability \( s(x) \) of investing when the state is \( x \). Their equilibrium uniqueness result depends on an assumption of continuous choice, meaning that for all information costs \( \theta > 0 \) and all parameterizations of the relevant utility function, \( s(x) \) is absolutely continuous on a compact interval for which \( q(x) \) has full support.
In our continuous state rational inattention problem (20), agents always choose posteriors that are differentiable, with a Lipschitz-continuous derivative. By assumption, the prior is also differentiable with a Lipschitz-continuous derivative. Therefore the function

\[ s(x) = \frac{q_{\text{invest}}(x)}{q(x)} \pi_{\text{invest}} \]

is differentiable with respect to \( x \) in the support of \( q \). By the Lipschitz-continuity of the derivatives \( q_{\text{invest}}'(x) \) and \( q'(x) \), and the fact that \( q(x) \) has full support over the relevant compact interval, the derivative of \( s(x) \) is bounded, and hence \( s(x) \) is absolutely continuous.

Thus, our proposal provides a micro-foundation for the continuous choice assumption required by Morris and Yang (2016), and hence for uniqueness in global games.

5.4 Linear-Quadratic Gaussian Environments

In this application, we consider the classic “Linear-Quadratic-Gaussian” (LQG) tracking problem, which is a major application of the standard theory of rational inattention (see, e.g., Sims (2010)). To consider this application, we extend the continuous-state version of our model, with the Fisher information cost function, to a continuous action space (we do not formally prove convergence). The message of this application, unlike the message of our three previous applications, is that the model predicts the same behavior regardless of whether the information cost is mutual information or Fisher information.

Let the state space \( X \) be the real line, and let the space of possible actions \( A \) be the real line as well. We assume that the DM’s task is to estimate the value of the state (i.e., to “track” variation in the state), with a reward given by \( u_a(x) = -(x - a)^2 \). In other words, the goal is to minimize the mean squared error of the DM’s estimate.

We assume that the prior distribution over the state space \( X \) is a Gaussian distribution, with mean \( \mu \) and variance \( \sigma^2 \). We assume that information costs are given by the Fisher-
information cost function, which we now generalize to allow for a continuum of actions.\footnote{We also generalize the model use the entire real line instead of a bounded interval as the state space.} It is convenient to consider the conditional probabilities \( \{p_a(x)\}_{a \in A} \), as in (21). Our problem is to choose the functions \( \{p_a(x)\}_{a \in A} \) so as to minimize

\[
\int_{-\infty}^{\infty} q(x) \int_{-\infty}^{\infty} [p_a(x)(a-x)^2 + \frac{\theta}{4} p'_a(x)]^2 d\alpha \text{d} \alpha,
\]

subject to the constraint that \( \sum_{a \in A} p_a(x) = 1 \) for all \( x \in X \).

This is a problem in the calculus of variations. We show in Technical Appendix, Section C.4, that if \( \theta < 4\sigma^2 \), the optimal information structure is equivalent to observing a noisy signal \( s = x + \varepsilon \), with the “measurement error” \( \varepsilon \sim N(0, \nu^2) \). Consequently, defining \( \beta = \frac{\sigma^2}{\sigma^2 + \nu^2} \), the DM’s posterior mean (and optimal action) is

\[
E[x|s] = (1 - \beta) \mu + \beta s,
\]

Moreover, the optimal degree of noise in the signal \( s \) is given by \( \nu^2 = \sigma^2 [2\sigma^2 \theta^{-\frac{1}{2}} - 1]^{-1} \), which is an increasing function of \( \theta \) for all \( \theta < 4\sigma^2 \).

In this solution, \( p_a(x) \) is a normal density function for each value of \( x \), with a mean that is a linear function of \( x \), and a variance that is independent of \( x \). As \( \theta \) approaches the bound \( 4\sigma^2 \), the optimal value of \( \nu^2 \) grows without bound, and \( \beta \) approaches zero; in the limit, the information structure becomes perfectly uninformative. We further show in the technical appendix that for any \( \theta \geq 4\sigma^2 \), it is optimal for the information structure to be purely uninformative, and for the DM to choose an action \( a = \mu \) regardless of the state. Therefore, this model, like the rational inattention model of Sims, allows for the possibility of a corner solution in which there is no attention at all paid to some features of the environment, despite the fact that tracking them would allow the DM to achieve a
higher level of welfare, and despite a finite information cost parameter $\theta$.

More generally, the main features of our results are exactly the same those of the LQG tracking problem with a mutual information. We include these results to show that, if one considers the tractability of the LQG problem an appealing feature of mutual information, the problem remains equally tractable (and the results equally sensible) with the Fisher information cost function.

### 6 Conclusion

What kinds of information cost functions should be used in static rational inattention problems? We have argued that two particular, related properties are desirable. First, the cost function should represent the results of a sequential evidence accumulation problem, one that can be related to the existing literature in psychology and neuroscience. Second, the cost function should capture the idea that certain states are easier or harder to discriminate than others. These two properties are linked, in our continuous time model, by the information cost matrix function, which controls both the ultimate choice probabilities (via the entropy function) and describes the difficulty of discriminating between pairs of states.

We have shown that all uniformly posterior separable cost functions satisfy the first property, and we have introduced the neighborhood-based cost functions as a subset of that also satisfy the second property. We have also extended our model to the continuous state case, and shown that Fisher information is the continuous state analog of the cost functions we advocate. In most of our applications, our proposed cost functions and mutual information generate very different predictions, but (reassuringly) they generate the same predictions for the linear-quadratic-Gaussian problem. We believe these neighborhood-based cost functions can and should be used in almost all applications of the rational inattention theory in the place of mutual information.

B Proofs

B.1 Proof of Lemma 1

In the continuation region, everywhere the value function is twice differentiable,

\[
\sup_{\sigma_t \in M(q_t)} \frac{1}{2} tr[\sigma_t^T D(q_t) V_{qq}(q_t) D(q_t) \sigma_t] = \kappa,
\]

subject to

\[
\frac{1}{2} tr[\sigma_t^T k(q_t) \sigma_t] \leq \chi.
\]

First, suppose that the constraint does not bind and a maximizing optimal policy exists:

\[
\frac{1}{2} tr[\sigma_t^* T k(q_t) \sigma_t^*] = a \chi,
\]

where \( \sigma_t^* \) is a maximizer, for some \( a \in [0,1) \) (\( a \geq 0 \) by the positive semi-definiteness of \( k(q_t) \)). For any \( c \in (1, a^{-1}) \), with \( a^{-1} = \infty \) for \( a = 0 \), if we used \( \sigma_t = c \sigma_t^* \) instead, the policy would be feasible and we would have

\[
\frac{1}{2} tr[\sigma_t^T D(q_t) V_{qq}(q_t) D(q_t) \sigma_t] = c^2 \kappa > \frac{1}{2} tr[\sigma_t^* T D(q_t) V_{qq}(q_t) D(q_t) \sigma_t^*] = \kappa,
\]

a contradiction by the fact that \( \kappa > 0 \). Therefore, either the constraint binds under the optimal policy or an optimal policy does not exist. The latter would require that, for some non-zero vector \( z \in \mathbb{R}^{|X|} \) with \( zz^T \in M(q_t) \),

\[
z^T D(q_t) V_{qq}(q_t) D(q_t) z > 0
\]

and \( z^T k(q_t) z = 0 \), but the null space of \( k(q_t) \) consists only of vectors whose elements are constant over the support of \( q_t \), and therefore satisfy \( q^T z \neq 0 \), implying that \( zz^T \notin M(q_t) \). Therefore, the constraint binds, and an optimal policy exists.

Using \( \theta \) as defined in the lemma, it must be the case (anywhere the DM chooses not to stop and the value function is twice differentiable) that

\[
\max_{\sigma_t \in M(q_t)} \frac{1}{2} tr[\sigma_t \sigma_t^T D(q_t) V_{qq}(q_t) D(q_t) - \theta k(q_t))] = 0.
\]
B.2 Proof of Theorem 1

Define $\phi(q_t)$ as the static value function in the statement of the theorem (we will prove that it is equal to $V(q_t)$, the value function of the dynamic problem). We first show that $\phi(q_t)$ satisfies the HJB equation, can be implemented by a particular strategy for the DM, and that any other strategy for the DM achieves weakly less utility. We begin by observing that

$$t^T k(q_t) \text{Diag}(q_t)^{-1} = 0 = t^T \text{Diag}(q_t) H_{qq}(q_t) = q^T_1 H_{qq}(q_t),$$

and therefore converse of Euler’s homogenous function theorem applies. That is, $H_q(q_t)$ is homogenous of degree zero, and $H(q_t)$ is homogeneous of degree one.

We start by showing that the function $\phi(q_t)$ is twice-differentiable in certain directions. Substituting the definition of the divergence into the statement of theorem,

$$\phi(q_0) = \max_{\pi \in \mathcal{P}(A), \{q_a \in \mathcal{P}(X)\}_{a \in A}} \sum_{a \in A} \pi(a) u_a^T \cdot q_a + \theta H(q_0) - \theta \sum_{a \in A} \pi(a) H(q_a),$$

subject to the same constraint. Define a new choice variable, $\hat{q}_a = \pi(a) q_a$. By definition, $\hat{q}_a \in \mathbb{R}_+^{|X|}$, and the constraint is $\sum_{a \in A} \hat{q}_a = q_0$. By the homogeneity of $H$, the objective is

$$\phi(q_0) = \max_{\pi \in \mathcal{P}(A), \{q_a \in \mathcal{P}(X)\}_{a \in A}, \{\hat{q}_a \in \mathcal{P}(X)\}_{a \in A}} \sum_{a \in A} u_a^T \cdot \hat{q}_a + \theta H(q_0) - \theta \sum_{a \in A} H(\hat{q}_a).$$

Any choice of $\hat{q}_a$ satisfying the constraint can be implemented by some choice of $\pi$ and $q_a$ in the following way: set $\pi(a) = t^T \hat{q}_a$, and (if $\pi(a) > 0$) set

$$q_a = \frac{\hat{q}_a}{\pi(a)}.$$

If $\pi(a) = 0$, set $q_a = q_0$. By construction, the constraint will require that $\pi(a) \leq 1$, $\sum_{a \in A} \pi(a) = 1$, and the fact that the elements of $q_a$ are weakly positive will ensure $\pi(a) \geq 0$. Similarly, $t^T q_a = 1$ for all $a \in A$, and the elements of $q_a$ are weakly greater than zero. Therefore, we can implement any set of $\hat{q}_a$ satisfying the constraints.

Rewriting the problem in Lagrangian form,

$$\phi(q_0) = \max_{\{\hat{q}_a \in \mathbb{R}^{|X|}\}_{a \in A}, \{\kappa \in \mathbb{R}^{|X|}\}_{a \in A}, \{v_a \in \mathbb{R}_+^{|X|}\}_{a \in A}} \min_{a \in A} \sum_{a \in A} u_a^T \cdot \hat{q}_a + \theta H(q_0) - \theta \sum_{a \in A} H(\hat{q}_a) + \kappa^T (q_0 - \sum_{a \in A} \hat{q}_a) + \sum_{a \in A} v_a \hat{q}_a.$$
Observe that $\phi(q_0)$ is convex in $q_0$. Suppose not: for some $q = \lambda q_0 + (1 - \lambda)q_1$, with $\lambda \in (0, 1)$, $\phi(q) < \lambda \phi(q_0) + (1 - \lambda)\phi(q_1)$. Consider a relaxed version of the problem in which the DM is allowed to choose two different $\hat{q}_a$ for each $a$. Because of the convexity of $H$, even with this option, the DM will set both of the $\hat{q}_a$ to the same value, and therefore the relaxed problem reaches the same value as the original problem. However, in the relaxed problem, choosing the optimal policies for $q_0$ and $q_1$ in the original problem, scaled by $\lambda$ and $(1 - \lambda)$ respectively, is feasible. It follows that $\phi(q) \geq \lambda \phi(q_0) + (1 - \lambda)\phi(q_1)$.

Note also that $\phi(q_0)$ is bounded on the interior of the simplex. It follows by Alexandrov’s theorem that it is twice-differentiable almost everywhere on the interior of the simplex.

By the convexity of $H$, the objective function is concave, and the constraints are affine and a feasible point exists. Therefore, the KKT conditions are necessary. Anywhere the objective function is continuously differentiable in the choice variables and in $q_0$, and therefore the envelope theorem applies. We have, by the envelope theorem,

$$\phi_q(q_0) = \theta H_q(q_0) + \kappa,$$

and the first-order conditions (for all $a \in A$ with $\hat{q}_a \neq \vec{0}$),

$$u_a - \theta H_q(\hat{q}_a) - \kappa + \nu_a = 0. \quad (22)$$

If $\hat{q}_a = \vec{0}$, we must have $q^T(u_a - \kappa) \leq \theta H(q)$ for all $q$, meaning that $u_a - \kappa$ is a sub-gradient of $H(q)$ at $q = 0$. In this case, we can define $\nu_a = \vec{0}$ and observe that the first-order condition holds for an appropriately-chosen sub-gradient. Define $\hat{q}_a(q_0)$, $\kappa(q_0)$, and $\nu_a(q_0)$ as functions that are solutions to the first-order conditions and constraints.

We next prove the “locally invariant posteriors” property described by Caplin et al. (2018b). Consider an alternative prior, $\tilde{q}_0 \in \mathcal{P}(X)$, such that

$$\tilde{q}_0 = \sum_{a \in A} \alpha(a) \hat{q}_a(q_0)$$

for some $\alpha(a) \geq 0$. Conjecture that $\hat{q}_a(\tilde{q}_0) = \alpha(a) \hat{q}_a(q_0)$, $\kappa(\tilde{q}_0) = \kappa(q_0)$, and $\nu_a(\tilde{q}_0) = \nu_a(q_0)$. By the homogeneity property,

$$H_q(\alpha(a) \hat{q}_a(q_0)) = H_q(\hat{q}_a(q_0)),$$

and therefore the first-order conditions are satisfied. By construction, the constraint is
satisfied, the complementary slackness conditions are satisfied, and \( \hat{q}_a \) and \( \nu_a \) are weakly positive. Therefore, all necessary conditions are satisfied, and by the concavity of the problem, this is sufficient. It follows that the conjecture is verified.

Consider a perturbation 

\[
q_0(\varepsilon; z) = q_0 + \varepsilon z,
\]

with \( z \in \mathbb{R}^{|X|} \), such that \( q_0(\varepsilon; z) \) remains in \( \mathcal{P}(X) \) for some \( \varepsilon > 0 \). If \( z \) is in the span of \( \hat{q}_a(q_0) \), then there exists a sufficiently small \( \varepsilon > 0 \) such that the above conjecture applies. In this case that \( \kappa \) is constant, and therefore \( \phi_q(q_0(\varepsilon; z)) \) is directionally differentiable with respect to \( \varepsilon \). If \( q_0(-\varepsilon; z) \in \mathcal{P}(X) \) for some \( \varepsilon > 0 \), then \( \phi_q \) is differentiable, with

\[
\phi_{qq}(q_0) \cdot z = \theta H_{qq}(q_0) \cdot z,
\]

proving twice-differentiability in this direction. This perturbation exists anywhere the span of \( \hat{q}_a(q_0) \) is strictly larger than the line segment connecting zero and \( q_0 \) (in other words, all \( \hat{q}_a(q_0) \) are not proportional to \( q_0 \)). Define this region as the continuation region, \( \Omega \). Outside of this region, all \( \hat{q}_a(q_0) \) are proportional to \( q_0 \), implying that

\[
\phi(q_0) = \max_{a \in A} u_a^T q_0,
\]

as required for the stopping region. Within the continuation region, the strict convexity of \( H(q_0) \) in all directions orthogonal to \( q_0 \) implies that, as required, 

\[
\phi(q_0) > \max_{a \in A} u_a^T q_0.
\]

Now consider an arbitrary perturbation \( z \) such that \( q_0(\varepsilon; z) \in \mathbb{R}^{|X|}_+ \) and \( q_0(-\varepsilon; z) \in \mathbb{R}^{|X|}_+ \) for some \( \varepsilon > 0 \). Observe that, by the constraint,

\[
\varepsilon z = \sum_{a \in A} (\hat{q}_a(\varepsilon; z) - \hat{q}_a(q_0)).
\]

It follows that

\[
(\kappa^T(q_0(\varepsilon; z)) - \kappa^T(q_0))\varepsilon z = \sum_{a \in A} (\kappa^T(q_0(\varepsilon; z)) - \kappa^T(q_0))(\hat{q}_a(\varepsilon; z) - \hat{q}_a(q_0)).
\]
By the first-order condition,
\[
(\kappa^T(q_0(\epsilon;z)) - \kappa^T(q_0))(\hat{q}_a(\epsilon;z) - \hat{q}_a(q_0)) = \\
[\theta H_q(\hat{q}_a(q_0)) - \theta H_q(\hat{q}_a(\epsilon;z)) + v^T_a(q_0(\epsilon;z)) - v^T_a(q_0)](\hat{q}_a(\epsilon;z) - \hat{q}_a(q_0)).
\]
Consider the term
\[
(v^T_a(q_0(\epsilon;z)) - v^T_a(q_0))(\hat{q}_a(\epsilon;z) - \hat{q}_a(q_0)) = \sum_{x \in X} (v^T_a(q_0(\epsilon;z)) - v^T_a(q_0)) e_x e^T_x (\hat{q}_a(\epsilon;z) - \hat{q}_a(q_0)).
\]
By the complementary slackness condition,
\[
(v^T_a(q_0(\epsilon;z)) - v^T_a(q_0))(\hat{q}_a(\epsilon;z) - \hat{q}_a(q_0)) = -v^T_a(q_0(\epsilon;z))\hat{q}_a(q_0) - v^T_a(q_0)\hat{q}_a(\epsilon;z) \leq 0.
\]
By the convexity of \(H\),
\[
\theta(H_q(\hat{q}_a(q_0)) - \theta H_q(\hat{q}_a(\epsilon;z)))(\hat{q}_a(\epsilon;z) - \hat{q}_a(q_0)) \leq 0.
\]
Therefore,
\[
(\kappa^T(q_0(\epsilon;z)) - \kappa^T(q_0))\epsilon z \leq 0.
\]
Thus, anywhere \(\phi\) is twice differentiable (almost everywhere on the interior of the simplex),
\[
\phi_{qq}(q) \preceq \theta H_{qq}(q),
\]
with equality in certain directions. Therefore, it satisfies the HJB equation almost everywhere in the continuation region. Moreover, by the convexity of \(\phi\),
\[
(H_q(q_0(\epsilon;z)) - H_q(q_0))^T \epsilon z \geq (\phi_q(q_0(\epsilon;z)) - \phi_q(q_0))^T \epsilon z \geq 0,
\]
implying that the “Hessian measure” (see Villani (2003)) associated with \(\phi_{qq}\) has no pure point component. This implies that \(\phi\) is continuously differentiable.

Next, we show that there is a strategy for the DM in the dynamic problem which can implement this value function. Suppose the DM starts with beliefs \(q_0\), and generates some \(\hat{q}_a(q_0)\) as described above. As shown previously, this can be mapped into a policy \(\pi(a,q_0)\)
and \( q_a(q_0) \), with the property that
\[
\sum_{a \in A} \pi(a, q_0) q_a(q_0) = q_0.
\]

We will construct a policy such that, for all times \( t \),
\[
q_t = \sum_{a \in A} \pi_t(a) q_a(q_0)
\]
for some \( \pi_t(a) \in \mathcal{P}(A) \). Let \( \Omega \) (the continuation region) be the set of \( q_t \) such that a \( \pi_t \in \mathcal{P}(A) \) satisfying the above property exists and \( \pi_t(a) < 1 \) for all \( a \in A \). The associated stopping rule will be the stop whenever \( \pi_t(a) = 1 \) for some \( a \in A \).

For all \( q_t \in \Omega \), there is a linear map from \( \mathcal{P}(A) \) to \( \Omega \), which we will denote \( Q(q_0) \):
\[
Q(q_0) \pi_t = q_t.
\]

Therefore, we must have
\[
Q(q_0) d\pi_t = \text{Diag}(q_t) \sigma_t dB_t.
\]

By the assumption that \(|X| \geq |A|\), there exists a \( |A| \times |X| \) matrix \( \sigma_{\pi,t} \) such that
\[
Q(q_0) \sigma_{\pi,t} = \text{Diag}(q_t) \sigma_t
\]
and \( d\pi_t = \sigma_{\pi,t} dB_t \). Define \( \hat{\phi}(\pi_t) = \phi(q_t) \). As shown above,
\[
Q^T(q_0) \phi_{qq}(q_t) Q(q_0)
\]
exists everywhere in \( \Omega \), and therefore
\[
\hat{\phi}(\pi_t) - \theta H(Q(q_0) \pi_t)
\]
is a martingale. We also have to scale \( \sigma_{\pi,t} \) to respect the constraint,
\[
\frac{1}{2} tr[\sigma_t \sigma_t^T k(q_t)] = \chi > 0.
\]
This can be rewritten as
\[
\frac{1}{2} \text{tr}[\sigma_{\pi,t} \sigma_{\pi,t}^T Q^T (q_0) \text{Diag}^+ (Q(q_0)\pi_t)k(Q(q_0)\pi_t))\text{Diag}^+ (Q(q_0)\pi_t)Q(q_0)] = \chi,
\]
where $\text{Diag}^+$ denotes the pseudo-inverse of the diagonal matrix.

By the positive-definiteness of $k$ in all directions except those constant in the support of $Q(q_0)\pi_t$, we will always have $\frac{1}{2} \text{tr}[\sigma_{\pi,t} \sigma_{\pi,t}^T] > 0$. Under the stopping rule described previously, the boundary will be hit a.s. as the horizon goes to infinity. As a result, by the martingale property described above, initializing $\pi_0(a) = \pi(a,q_0)$,
\[
\hat{\phi}(\pi_0) = E_0[\hat{\phi}(\pi_\tau) - \theta H(Q(q_0)\pi_\tau) + \theta H(Q(q_0)\pi_0)].
\]

By Ito’s lemma,
\[
\theta H(Q(q_0)\pi_\tau) - \theta H(Q(q_0)\pi_0) = \int_0^\tau \chi \theta dt = \mu \tau.
\]

By the value-matching property of $\phi$, $\hat{\phi}(\pi_\tau) = \hat{u}(Q(q_0)\pi_\tau)$. It follows that, as required,
\[
\phi(q_0) = \hat{\phi}(\pi_0) = E_0[\hat{u}(q_\tau) - \mu \tau].
\]

Finally, we verify that alternative policies are sub-optimal. Consider an arbitrary control process $\sigma_t$ and stopping rule described by the stopping time $\tau$. We have, by the convexity of $\phi$ and the generalized Ito formula for convex functions (noting that we have shown that the Hessian measure associated with $\phi_{qq}$ has no pure point component), interpreting $\phi_{qq}$ in a distributional sense,
\[
E_0[\phi(q_\tau)] - \phi(q_0) = \frac{1}{2} E_0[\int_0^\tau \text{tr}[\sigma_t^T D(q_t) \phi_{qq}(q_t) D(q_t) \sigma_t]dt].
\]

By the feasibility of the policies, anywhere in the continuation region of the optimal policy,
\[
\frac{1}{2} \text{tr}[\sigma_t^T D(q_t) \phi_{qq}(q_t) D(q_t) \sigma_t] \leq \frac{1}{2} \theta \text{tr}[\sigma_t^T k(q_t) \sigma_t] \leq \theta \chi.
\]

In the stopping region of the optimal policy,
\[
\frac{1}{2} \text{tr}[\sigma_t^T D(q_t) \phi_{qq}(q_t) D(q_t) \sigma_t] = 0 < \theta \chi.
\]
Therefore,
\[ \phi(q_0) \geq E_0[\phi(q_\tau)] - \int_0^\tau \theta \chi dt. \]
By inequality \( \phi(q_\tau) \geq \hat{u}(q_\tau), \phi(q_0) \geq E_0[\hat{u}(q_\tau) - \mu \tau] \) for all policies, verifying optimality.

### B.3 Proof of Lemma 2

We have, for any interior \( q \),
\[
H_N(q; \rho) = -\sum_{i \in \mathcal{I}} c_i \bar{q}_i H_{Gen}(q_i; \rho) \\
= \sum_{i \in \mathcal{I}} c_i \bar{q}_i \frac{1}{|X_i|} \sum_{x \in X_i} \left\{ (\frac{e_T^T q}{|X_i|})^{2-\rho - 1} \right\}. 
\]

Differentiating,
\[
\frac{\partial H_N(q; \rho)}{\partial q_x} = -\sum_{i \in \mathcal{I}, x' \in X_i} c_i |X_i|^{1-\rho} \frac{1}{\rho - 1} q_i^{\rho - 1} (e_{x'}^T q)^{1-\rho} \\
+ \sum_{i \in \mathcal{I}, x' \in X_i} c_i |X_i|^{1-\rho} \frac{1}{\rho - 2} q_i^{\rho - 2} \sum_{x'' \in X_i} (e_{x''}^T q)^{2-\rho} \\
- \sum_{i \in \mathcal{I}, x' \in X_i} c_i \frac{1}{|X_i|} \frac{1}{\rho - 1}. 
\]

Differentiating again,
\[
\frac{\partial^2 H_N(q; \rho)}{\partial q_{x'} \partial q_{x''}} = \delta_{x',x''} \sum_{i \in \mathcal{I}, x' \in X_i} c_i |X_i|^{1-\rho} q_i^{\rho - 1} \bar{q}_i^{\rho - 1} q_{x'}^{1-\rho} \\
- \sum_{i \in \mathcal{I}, x',x'' \in X_i} c_i |X_i|^{1-\rho} q_i^{\rho - 2} q_{x'}^{1-\rho} \\
- \sum_{i \in \mathcal{I}, x',x'' \in X_i} c_i |X_i|^{1-\rho} q_i^{\rho - 2} q_{x''}^{1-\rho} \\
+ \sum_{i \in \mathcal{I}, x',x'' \in X_i} c_i |X_i|^{1-\rho} q_i^{\rho - 3} \sum_{x''' \in X_i} q_{x'''}^{2-\rho}. 
\]
Thus,
\[
q_x' \left( \frac{\partial^2 H_N(q; \rho)}{\partial q_x' \partial q_x''} \right) q_x'' = \sum_{i \in I} c_i |X_i|^{1-\rho} \bar{q}_i \{ \delta_{x',x''} \left( \frac{q_x'}{q_i} \right)^{2-\rho} - \left( \frac{q_x'}{q_i} \right)^{2-\rho} \left( \frac{q_x''}{q_i} \right) + \left( \frac{q_x'}{q_i} \right) \left( \sum_{x'' \in X_i} \left( \frac{q_{x''}}{q_i} \right)^{2-\rho} \right) \}. 
\]

Note that this equation also holds in the \( \rho = 2 \) and \( \rho = 1 \) cases. We can write this as
\[
q_x' \left( \frac{\partial^2 H_N(q; \rho)}{\partial q_x' \partial q_x''} \right) q_x'' = \sum_{i \in I} c_i |X_i|^{1-\rho} \bar{q}_i e_x^T E_i m(q_i) E_i e_x'',
\]
where
\[
m(q_i) = \text{Diag}(q_i)^{2-\rho} - \text{Diag}(q_i)^{2-\rho} t q_i^T - q_i^T \text{Diag}(q_i)^{2-\rho} + q_i t \text{Diag}(q_i)^{2-\rho} t q_i^T \\
= (I - t q_i^T) \text{Diag}(q_i)^{2-\rho} (I - t q_i^T).
\]

The result immediately follows in the \( \rho = 2 \) case. For any \( \rho \neq 2 \),
\[
m(q_i)^{\frac{1}{2-\rho}} = (I - t q_i^T) \text{Diag}(q_i)(I - t q_i^T) \\
= \text{Diag}(q) - q_i q_i^T - q_i T + q_i T \\
= g^+(q_i).
\]

If \( \rho < 2 \), \( H_N(q; \rho) \) is a bounded convex function on the relative interior of the simplex, and hence by theorem 10.3 of Rockafellar (1970) there is a unique extension to the simplex.

**B.4 Proof of Lemma 3**

First, note that if \( \rho \geq 2 \) and \( q_x \) does not have full support, then \( p_x \) will not have full support for the state \( x \) such that \( e_x^T q_x = 0 \), and we will have \( D_\rho(p_x||p E_i q_i) = \infty \) for any \( i \) with \( x \in X_i \), as required. For \( \rho < 2 \), continuity holds, and therefore both boundary cases are satisfied, provided the result holds for interior \( q_s \).

To prove this claim, it is sufficient to show that, if all \( q_s \) are interior,
\[
\sum_{i \in I} c_i |X_i|^{1-\rho} \bar{q}_i^{\rho-1} \sum_{x \in X_i} (e_x^T q)^{2-\rho} D_\rho(p_x||p E_i^T q_i) = -H_N(q) + \sum_{s \in S} (e_s^T p q) H_N(e_s^T p \text{Diag}(q)).
\]
Using Lemma 2,

\[ \sum_{s \in \mathcal{S}} \pi_s H_N(q_s) = \sum_{s \in \mathcal{S}, \pi_s > 0} \pi_s \sum_{i \in \mathcal{I}} c_i \tilde{q}_{i,s} \frac{1}{|X_i|} \frac{1}{(\rho - 2)(\rho - 1)} \sum_{x \in X_i} \left\{ \frac{(e_x^T q_s)}{1}^{2 - \rho} - 1 \right\}. \]

Using Bayes’ rule, \( \pi_s \tilde{q}_{i,s} = \tilde{q}_{i,s} \tilde{p}_{i,s} \), where \( \tilde{p}_{i,s} = p E_i^T q_i \), and therefore

\[ \sum_{s \in \mathcal{S}} \pi_s H_N(q_s) = \sum_{i \in \mathcal{I}} c_i |X_i|^{1 - \rho} \frac{1}{\tilde{q}_i^{\rho - 1}} \frac{1}{(\rho - 2)(\rho - 1)} \sum_{x \in X_i} (e_x^T q_i)^{2 - \rho} \sum_{s \in \mathcal{S}, \pi_s > 0} \tilde{p}_{i,s}^{\rho - 1} \left( e_x^T p e_x \right)^{2 - \rho} \]

\[ - \sum_{i \in \mathcal{I}} c_i \tilde{q}_i \frac{1}{(\rho - 2)(\rho - 1)}. \]

Therefore,

\[ -H_N(q) + \sum_{s \in \mathcal{S}} \pi_s H_N(q_s) = \sum_{i \in \mathcal{I}} c_i |X_i|^{1 - \rho} \frac{1}{\tilde{q}_i^{\rho - 1}} \sum_{x \in X_i} (e_x^T q_i)^{2 - \rho} D_\rho (p_x || p E_i^T q_i), \]

as required. The proof is essentially identical in the \( \rho = 1 \) and \( \rho = 2 \) cases.
C Technical Appendix

C.1 A Jump-Only Continuous Time Model

In this section, we describe an alternative to the diffusion-based model presented in section §2, in which the DM updates her beliefs via a controlled Poisson process. For a derivation of this model, see Hébert and Woodford (2018). We informally demonstrate that, if the cost of the Poisson signal is described by a Bregman divergence, Theorem 1 continues to describe the DM’s value function, even though the beliefs follow a Poisson process as opposed to a diffusion. Formally, Theorem 1 and the results in Hébert and Woodford (2018), taken together, imply this result.

We suppose that the DM’s beliefs follows the stochastic process

\[ dq_t = -\psi_t y_t dt + y_t dJ_t, \]

where \( dJ_t \) is a Poisson process with intensity \( \psi_t \) (controlled by the DM), and \( y_t \) is direction beliefs jump (also controlled by the DM). There is a trivial restriction to ensure beliefs stay in the simplex: \( y_t + q_t \in \mathcal{P}(X) \) (let \( Y(q_t) \) denote the set of \( y_t \) for which this holds). There is also a non-trivial restriction,

\[ \psi_t D^*(q_t + y_t || q_t) \leq \chi, \]

where \( D^* \) is a divergence, convex in its first argument, and \( \chi \) is a positive constant that indexes the tightness of the constraint.

We will assume that \( D^* \) satisfies, for all sets of signals \( S \), all \( \pi \in \mathcal{P}(S) \), and \( q, q', \{ q_s \}_{s \in S} \in \mathcal{P}(X) \) such that \( \sum_{s \in S} \pi_s q_s = q' \),

\[ D^*(q' || q) + \sum_{s \in S} \pi_s D^*(q_s || q') \geq \sum_{s \in S} \pi_s D^*(q_s || q). \]

Note that a Bregman divergence (as defined in equation (11)) satisfies this condition with equality. In Hébert and Woodford (2018), we prove that this condition leads to immediate stopping after jumps in the dynamic problem.

The remainder of the model is essentially identical to the one described in section §2.
The DM maximizes her expected payoff, subject to the aforementioned constraints:

\[ V(q_t) = \sup_{\{y_t \in Y(q_t), \psi_t \geq 0\}} E_t[\hat{u}(q_\tau) - \kappa(\tau - t)]. \]

Anywhere the value function is differentiable and the DM does not choose to stop, the Hamilton-Jacobi-Bellman (HJB) equation associated with this problem is

\[ \sup_{y_t \in Y(q_t), \psi_t \geq 0} \psi_t (V(q_t + y_t) - V(q_t) - V_q(q_t)y_t) dt = \kappa dt, \]

subject to \( \psi^* H(q_t + y_t || q_t) \leq \chi \).

It immediately follows, by \( \kappa > 0 \), that \( \psi^*_t > 0 \) and the constraint must bind, and thus

\[ V(q_t + y^*_t) - V(q_t) - V_q(q_t)y^*_t = \theta D^*(q_t + y^*_t || q_t), \]

where \( \theta = \chi^{-1} \kappa \). Optimality requires that

\[ V(q_t + y^*_t) - V(q_t) - \theta H(q_t + y^*_t || q_t) \geq V(q_t + y' - V_q(q_t)y' - \theta D^*(q_t + y' || q_t) \]

for all \( y' \in Y(q_t) \).

We now define, from the divergence \( D^* \) and the initial beliefs \( q_0 \), a Bregman divergence \( D_H(\cdot||\cdot) \), from an entropy function

\[ H(q) = D^*(q || q_0). \]

We will guess and verify that the value function described by Theorem 1 satisfies these equations, with this entropy function. We will assume, to keep the exposition short, that the optimal posteriors are interior and that all actions are chosen with positive probability, but neither requirement is necessary.

The envelope theorem and first-order conditions from the static problem (equation (14)) apply. By the homogeneity of degree one of the \( H \) function,

\[ q_a^T (u_a - \kappa - \theta H_q(q_a) + \theta H_q(q_0)) = q_a^T (u_a - \kappa) - \theta D_H(q_a || q_0). \]

Plugging this into the definition of the static value function, \( V(q_0) = q_0^T \kappa \). Therefore, using
the envelope theorem and the above expression,
\[ q_a^T \cdot u_a - (q_a - q_0)^T \cdot V_q(q_0) - \theta D_H(q_a||q_0) - V(q_0) = 0. \]
Thus, if \( V(q_a) = q_a^T \cdot u_a \), this expression is
\[ V(q_a) - V(q_0) - (q_a - q_0)^T V_q(q_0) - \theta D_H(q_a||q_0) = 0, \]
and \( q_a \) is a maximizer of this expression. We appeal to the “Locally Invariant Posteriors” property shown by Caplin et al. (2018b): \( q_a \) as a prior is a convex combination of the posteriors chosen from \( q_0 \), and therefore the same set of posteriors will be chosen with \( q_a \) as a prior, and hence it must be the case that \( V(q_a) = q_a^T \cdot u_a \), as required.

By the definition of \( D_H \),
\[ V(q_a) - V(q_0) - (q_a - q_0)^T V_q(q_0) = \theta D^*(q_a||q_0), \]
and hence the first-order condition in the dynamic problem is satisfied. For any \( q' \in \mathcal{P}(X) \),
\[ V(q') - V(q_0) - (q' - q_0)^T V_q(q_0) \leq \theta D_H(q'||q_0). \]
Consequently,
\[
\varepsilon(V(q') - V(q_0) - (q' - q_0)^T V_q(q_0)) + (1 - \varepsilon)(V(q_0 - \varepsilon(q' - q_0)) - V(q_0) + \varepsilon(q' - q_0)^T V_q(q_0) \\
\leq \varepsilon \theta D_H(q'||q_0) + (1 - \varepsilon) \theta D_H(V(q_0 - \varepsilon(q' - q_0)||q_0) \\
\leq \varepsilon \theta D^*(q'||q_0) + (1 - \varepsilon) \theta D^*(V(q_0 - \varepsilon(q' - q_0)||q_0). \]
Dividing by \( \varepsilon \) and taking limits,
\[ V(q') - V(q_0) - (q' - q_0)^T V_q(q_0) \leq D^*(q'||q_0), \]
and hence optimality is satisfied.

Therefore, for any \( y = q_a - q_0 \), the static value function solves the HJB equation. Formalizing this proof would require dealing with boundaries, and verification. Both of these issues are technical but relatively straightforward in this context.
C.2 Convergence to the Continuous State Model

For each of a sequence of values for the integer $M$, we assume a neighborhood structure of the kind discussed in section 4.2 with $M + 1$ states. The set of states is ordered, $X^M = \{0, 1, \ldots, M\}$, and each pair of adjacent states forms a neighborhood, $X_i = \{i, i+1\}$, for all $i \in \{0, 1, \ldots, M - 1\}$. We will also assume that there is an $M + 1$st neighborhood containing all of the states. Note that $M$ indexes both the number of states and the number of neighborhoods. We consider the limit as $M \to \infty$.

To study this limit, we need to define how the prior beliefs, $q_M$, and the magnitude of the information costs vary with $M$. For the initial beliefs, we shall assume that there is a differentiable probability density function $q : [0, 1] \to \mathbb{R}^+$, with full support on the unit interval and with a derivative that is Lipschitz continuous. Using this function, we define, for any $i \in X^M$,

$$e_i^T q_M = \int_{\frac{i}{M+1}}^{\frac{i+1}{M+1}} q(x) dx.$$ 

That is, for each value of $M$, the prior $q_M$ is assumed to be a discrete approximation to the p.d.f. $q(x)$, which becomes increasingly accurate as $M \to \infty$.

For our neighborhood structures, we assume that the constants associated with the cost of each neighborhood, $c_j$, are equal to $M^2$ for all $j < M$, and $M^{-1}$ for $j = M$. In this particular example, the scaling ensures that the DM is neither able to determine the state with certainty, nor prevented from gathering any useful information, even as $M$ is made arbitrarily large; moreover, the scaling ensures that the neighborhood containing all states plays no role in the limiting behavior, so that in the limit all information costs are local. We also scale the entire cost function by a constant, $\theta > 0$.

We also need to define the set of actions, and the utility from those actions. We will assume the set of actions, $A$, remains fixed as $N$ grows, and define the utility from a particular action, in a particular state, as

$$e_i^T u_{a,M} = \frac{\int_{\frac{i}{M+1}}^{\frac{i+1}{M+1}} q(x) u_a(x) dx}{e_i^T q_M}.$$ 

Here, the utility $u_a : [0, 1] \to \mathbb{R}$ is a bounded measurable function for each action $a \in A$.\footnote{Note that we do not require the payoff resulting from an action to be a continuous function of $x$ at all points, though it will be continuous almost everywhere. This allows for the possibility that a DM’s payoffs change discontinuously when the state $x$ crosses some threshold, as in some of our applications.}
In other words, as $M$ grows large, the prior converges to $q(x)$ and the utilities converge to the functions $u_a(x)$.

We consider only the case of neighborhood cost functions with $\rho = 1$. Under these assumptions, the static model of Theorem 1 can be written as

$$V_N(q_M; M) = \max_{\pi_M \in \mathcal{P}(A), \{q_{a,M} \in \mathcal{P}(X^M)\}_{a \in A}} \sum_{a \in A} \pi_M(a)(u_{a,M}^T q_{a,M}) - \theta \sum_{a \in A} \pi_M(a)D_N(q_{a,M} || q_M; M),$$

subject to the constraint that

$$\sum_{a \in A} \pi_N(a) q_{a,M} = q_M.$$

Here $D_N$ denotes the divergence associated with the neighborhood-based cost function introduced above, specialized to the particular neighborhood structure of this section and $\rho = 1$:

$$D_N(q_{a,M} || q_M; M) = M^2 (H_N(q_{a,M}; 1, M) - H_N(q_M; 1, M)) + M^{-1} (H^S(q_M; M) - H^S(q_{a,M}; M)),$$

where $H_N$ is defined by equation (18) in the main text and $H^S$ is Shannon’s entropy.

The following theorem shows that the solution to this problem, both in terms of the value function and the optimal policies, converges to the solution of a static rational inattention problem with a continuous state space.

**Theorem 2.** Consider the sequence of finite-state-space static rational inattention problems (23), with progressively larger state spaces indexed by the natural numbers $M$. There exists a sub-sequence of integers $n \in \mathbb{N}$ for which the solutions to the sub-sequence of problems converge, in the sense that, for some $\pi^* \in \mathcal{P}(A)$ and $\{q^*_a \in \mathcal{P}([0, 1])\}_{a \in A}$,

i) $\lim_{n \to \infty} V_N(q_n; n) = V_N(q)$;

ii) $\lim_{n \to \infty} \pi^*_n = \pi^*$; and

iii) for all $a \in A$ and all $x \in [0, 1]$, $\lim_{n \to \infty} \sum_{i=0}^{\lfloor xn \rfloor} e_i^T q^*_a = \int_0^x q^*_a(y)dy$.

Moreover, the limiting value function $V_N(q)$ is the value function for the following continuous-
state-space static rational inattention problem:

\[
V_N(q) = \sup_{\pi \in \mathcal{P}(A), \{q_a \in \mathcal{P}_{\text{LipG}}([0,1])\}_{a \in A}} \sum_{a \in A} \pi(a) \int_{\text{supp}(q)} u_a(x) q_a(x) dx \\
- \frac{\theta}{4} \sum_{a \in A} \{ \pi(a) \int_0^1 \frac{(q'_a(x))^2}{q_a(x)} dx \} + \frac{\theta}{4} \int_0^1 \frac{(q'(x))^2}{q(x)} dx,
\]

subject to the constraint that, for all \( x \in [0,1] \),

\[
\sum_{a \in A} \pi(a) q_a(x) = q(x), \tag{24}
\]

and where \( \mathcal{P}_{\text{LipG}}([0,1]) \) denotes the set of differentiable probability density functions with full support on \([0,1]\), whose derivatives are Lipschitz-continuous. Furthermore, the limiting action probabilities \( \pi^*(a) \) and posteriors \( q^*_a \) are the optimal policies for this continuous-state-space problem.

**Proof.** See the technical appendix, section C.6. □

This theorem demonstrates that the value function, choice probabilities, and posterior beliefs of the discrete state problem converge to the value function, choice probabilities, and posterior beliefs associated with a continuous state problem. The continuous state problem uses a particular cost function, the expected value of the Fisher information \( I_{\text{Fisher}}(x; p) \), defined locally for each element of the continuum of possible states \( x \), with the expectation taken with respect to the prior over possible states. The posterior beliefs in the continuous state problem, \( q_a(x) \), are required to be differentiable, with a Lipschitz-continuous derivative, on their support. This is a result; the limiting posterior beliefs of the discrete state problem will have these properties. This restriction also ensures that the Fisher information is finite, so that the optimization associated with the continuous state problem is well-behaved.

The static rational inattention problem for the limiting case of a continuous state space can be given an alternative, equivalent formulation, in which the objects of choice are the conditional probabilities of taking different actions in the different possible states, rather than the posteriors associated with different actions. This is essentially the continuous state analog of Lemma 3.
Lemma 4. Consider the alternative continuous-state-space static rational inattention problem:

\[ \bar{V}_N(q) = \sup_{p \in \mathcal{P}_{\text{LipG}}(A)} \int_0^1 q(x) \sum_{a \in A} p_a(x) u_a(x) dx - \frac{\theta}{4} \int_0^1 q(x) I_{\text{Fisher}}(x; p) dx, \]

where \( \mathcal{P}_{\text{LipG}}(A) \) is the set of mappings \( p : [0, 1] \to \mathcal{P}(A) \) such that for each action \( a \), the function \( p_a(x) \) is a differentiable function of \( x \) with a Lipschitz-continuous derivative, and for any information structure \( p \in \mathcal{P}_{\text{LipG}}(A) \), the Fisher information at state \( x \in X \) is defined as

\[ I_{\text{Fisher}}(x; p) \equiv \sum_{a \in A} \left( \frac{p_a'(x)}{p_a(x)} \right)^2. \]

This problem is equivalent to the one defined in Theorem 2, in the sense that the information structure \( p^* \) that solves this problem defines action probabilities and posteriors

\[ \pi^*(a) = \int_0^1 q(x)p^*_a(x), \quad q^*_a(x) = \frac{q(x)p^*_a(x)}{\pi^*(a)} \tag{25} \]

that solve the problem in Theorem 2, and conversely, the action probabilities and posteriors \( \{\pi^*(a), q^*_a\} \) that solve the problem stated in the theorem define state-contingent action probabilities

\[ p^*_a(x) = \frac{\pi^*(a)q^*_a(x)}{q(x)} \tag{26} \]

that solve the problem stated here. Moreover, the maximum achievable value is the same for both problems: \( \bar{V}_N(q) = V_N(q) \).

Proof. See the appendix, section C.7.

C.3 Security Design and Acceptance with Certainty

In this section, we discuss the optimal security design application, and consider the possibility that the seller designs the security to induce the buyer to accept with probability one. In other words, the buyer’s “consideration set” in his rational inattention problem consists only of \( L \), instead of both \( L \) and \( R \). As mentioned in the text, we have chosen the parameters of our numerical example to ensure that, for all of the cost functions, the seller is better off for any \( x \in [0, 1] \), we use the notation \( p_a(x) \) to indicate the probability of action \( a \) implied by the probability distribution \( p(x) \in \mathcal{P}(A) \).
inducing information acquisition ($\pi_L < 1$) than avoiding information acquisition ($\pi_L = 1$). Note that the $\pi_L = 0$ case is equivalent to trading a “nothing” security at zero price, and hence assuming $\pi_L > 0$ is without loss of generality.

Consider the buyer’s problem,

$$V(q; s, K) = \max_{\pi_L \in [0,1], q_L, q_R \in \mathcal{P}(X)} \pi_L q_L^T (s - Kt) - \theta \pi_L D_H(q_L||q) - \theta (1 - \pi_L) D_H(q_R||q),$$

subject to the constraint that $\pi_L q_L + (1 - \pi_L) q_R = q$. Rewrite the choice variables as $\hat{q}_L = \pi_L q_L$ and $\hat{q}_R = (1 - \pi_L) q_R$, and use the homogeneity of the $H$ function, so that the problem is

$$V(q; s, K) = \max_{\hat{q}_L, \hat{q}_R \in \mathbb{R}_+^|X|} \hat{q}_L^T (s - Kt) - \theta D_H(\hat{q}_L||q) - \theta D_H(\hat{q}_R||q),$$

subject to $\hat{q}_L + \hat{q}_R = q$. Observe that the objective is concave and the constraints linear, so it suffices to consider local perturbations.

Suppose that it is optimal to set $\pi_L = 1$, implying $\hat{q}_L = q$. Consider a perturbation to $\hat{q}_L = q - \varepsilon q_R$, $\hat{q}_R = \varepsilon q_R$, for any arbitrary $q_R \in \mathcal{P}(X)$. For such a perturbation to reduce utility, we must have

$$-\varepsilon q_R^T (s - Kt) - \theta D_H(q - \varepsilon q_R||q) - \theta \varepsilon D_H(q_R||q) \leq 0.$$

Taking the limit as $\varepsilon \to 0^+$, we must have, for all $q_R$, and hence for the minimizer,

$$\min_{q_R \in \mathcal{P}(X)} q_R^T (s - Kt) + \theta D_H(q_R||q) \geq 0.$$

If this condition is satisfied, it is at least weakly optimal for the buyer to choose $\pi_L = 1$ and gather no information. Consequently, the Lagrangian version of the optimal security design problem, subject to the constraint of inducing no information acquisition, is

$$\max_{s \in \mathbb{R}_+^|X|, K \geq 0, \lambda \geq 0, q_R \in \mathcal{P}(X), \omega \in \mathbb{R}_+^{|X|}} \min_{\lambda \geq 0} q^T (Kt - \beta s) + \lambda (q_R^T (s - Kt) + \theta D_H(q_R||q)) + \omega^T (v - s),$$

where $\lambda$ is the multiplier on the no-information-gathering constraint and $\omega$ is the multiplier.
on the upper-bound of the limited liability requirement.

Defining $\tilde{q}_R = \lambda q_R$, the dual of this problem is

$$
\min_{\tilde{q}_R \in \mathbb{R}^{\mid X\mid}, \omega \in \mathbb{R}^{\mid X\mid}, s \in \mathbb{R}^{\mid X\mid}, \upsilon \geq 0} \quad q^T (Kt - \beta s) + \tilde{q}_R^T (s - Kt) + \theta D_H (\tilde{q}_R \| q) + \omega^T (\upsilon - s),
$$

which can be understood as

$$
\min_{\tilde{q}_R \in \mathbb{R}^{\mid X\mid}, \omega \in \mathbb{R}^{\mid X\mid}} \quad \theta D_H (\tilde{q}_R \| q) + \omega^T \upsilon,
$$

subject to

$$
\tilde{q}_R - \beta q - \omega \leq 0,
$$

$$
1 - q^T t \leq 0.
$$

The multipliers of this convex minimization problem are the optimal security design and price. After solving the problem for $\tilde{q}_R$ and $\omega$, we can use the first-order condition to recover the security design:

$$
s - Kt = H_q (q) - H_q (\tilde{q}_R).
$$

We use the convention that in the lowest state, the asset value is zero ($e_0^T \upsilon = 0$), and therefore $e_0^T s = 0$, and hence

$$
e_s^T s = (e_x - e_0)^T (H_q (q) - H_q (\tilde{q}_R)).
$$

To implement the problem with the additional requirement of monotonicity for the security design, write the monotonicity requirement as $M s \gg 0$, where $M$ is an $|X| - 1 \times |X|$ matrix. The dual problem is

$$
\min_{\tilde{q}_R \in \mathbb{R}^{\mid X\mid}, \omega \in \mathbb{R}^{\mid X\mid}, \rho \in \mathbb{R}^{\mid X\mid}} \theta D_H (\tilde{q}_R \| q) + \omega^T \upsilon,
$$

subject to

$$
\tilde{q}_R - \beta q - \omega + M^T \rho \leq 0,
$$

$$
1 - q^T t \leq 0.
$$

As mentioned above, under our parameters it is not optimal for the seller to avoid in-
formation acquisition. For completeness, we present the optimal securities that avoid information acquisition below. Note the shapes of these securities are very similar to their optimal counterparts, although the level is often quite different.

Figure 5: Optimal Security Designs that Avoid Info. Acquisition by Entropy Function

Figure 6: Optimal Monotone Security Designs that Avoid Info Acquisition by Entropy Function
C.4 The Linear-Quadratic-Gaussian Tracking Problem

Here we solve the problem in the calculus of variations stated in Section 5.4. We begin by noting that the objective (21) that we wish to minimize is of the form

\[ \int_X q(x) \int_A F(a, p_a(x), p'_a(x); x) \, da \, dx, \]

where for each pair \((x, a)\), the function

\[ F(a, f, g; x) \equiv f \cdot (a - x)^2 + \frac{\theta g^2}{4 f} \]

is a convex function of the arguments \((f, g)\) everywhere on its domain (the half-plane on which \(f > 0\)). This can be seen from the fact that (for any fixed values of \((x, a)\)) \(F(f, g)\) is equal to \(f\) times a convex function of \(g/f\).

Given the convexity of the objective, the first-order conditions are both necessary and sufficient for an optimum. The relevant first-order conditions are furthermore the same as those for minimization of the Lagrangian

\[ \int_X q(x) \int_A L(a, p_a(x), p'_a(x); x) \, da \, dx, \]

where

\[ L(a, f, g; x) = F(a, f, g; x) + \phi(x) f. \quad (27) \]

Here \(\phi(x)\) is the Lagrange multiplier associated with the constraint

\[ \int_A p_a(x) \, da = 1 \quad (28) \]

for each \(x \in X\), as is required in order for \(p_a(x)\) to be a probability density function.

For given Lagrange multipliers, the problem of minimizing the Lagrangian can further be expressed as a separate minimization problem for each possible action \(a\). Then if we can find a function \(\phi(x)\) and a function \(p_a(x)\) for each \(a \in A\), with \(p_a(x) > 0\) for all \(x\), such that (i) for each \(a \in A\), the function \(p_a(x)\) minimizes

\[ \int_X q(x)L(a, p_a(x), p'_a(x); x) \, dx, \quad (29) \]
and (ii) condition (28) holds for all \( x \in X \), then we will have derived an optimal information structure.

For the problem of choosing a function \( p_a(x) \) to minimize (29), the first-order conditions are given by the Euler-Lagrange equations

\[
q(x) \frac{\partial L}{\partial f}(a, p_a(x), p'_a(x); x) = \frac{d}{dx} \left[ q(x) \frac{\partial L}{\partial g}(a, p_a(x), p'_a(x); x) \right],
\]

or equivalently,

\[
\frac{\partial L}{\partial f}(a, p_a(x), p'_a(x); x) = \frac{\partial L}{\partial g}(a, p_a(x), p'_a(x); x) \cdot \frac{d}{dx} \left[ \log q(x) \right] + \frac{d}{dx} \left[ \frac{\partial L}{\partial g}(a, p_a(x), p'_a(x); x) \right].
\]

In the case of the objective function (27), we have

\[
\frac{\partial L}{\partial f} = (a - x)^2 - \frac{\theta}{4} (v'_a(x))^2 + \varphi(x),
\]

\[
\frac{\partial L}{\partial g} = \frac{\theta}{2} v'_a(x),
\]

where \( v_a(x) \equiv \log p_a(x) \). Under our assumption of a Gaussian prior, we also have

\[
\frac{d}{dx} \left[ \log q(x) \right] = \frac{\mu - x}{\sigma^2}.
\]

Substituting these expressions, the Euler-Lagrange equations take the form

\[
(a - x)^2 + \varphi(x) - \frac{\theta}{4} (v'_a(x))^2 = \frac{\theta}{2} \frac{\mu - x}{\sigma^2} v'_a(x) + \frac{\theta}{2} v''_a(x)
\]

for all \( x \) and \( a \).

In the case that \( \theta < 4\sigma^4 \), these equations have a solution given by

\[
v'_a(x) = \lambda [a - \beta x - (1 - \beta)\mu],
\]

\[
\varphi(x) = [\beta x + (1 - \beta)\mu] [2 - (\beta x + (1 - \beta)\mu)] - x^2 - 2\beta (1 - \beta) \sigma^2,
\]

where

\[
\lambda \equiv \frac{2}{\theta^{1/2}} > 0, \quad \beta \equiv 1 - \frac{\theta^{1/2}}{2\sigma^2},
\]

which implies (given the bound on \( \theta \)) that \( 0 < \beta < 1 \). Equation (30) is further observed to

\[
67
\]
correspond to the density function \( p_a(x) \) for a Gaussian distribution with mean

\[
E[a|x] = \beta x + (1 - \beta)\mu
\]  
(32)

and variance

\[
\text{var}[a|x] = \frac{\beta}{\lambda} = \sigma^2 \beta (1 - \beta) > 0. 
\]  
(33)

This solution for the distribution of \( a \) conditional on \( x \) further corresponds to a noisy representation of the state, \( s = x + \varepsilon \), where the “observation error” \( \varepsilon \) is normally distributed, with mean zero and a variance \( \nu^2 \), and independent of the value of \( x \); and an estimate \( a \) of the state given by the expectation of \( x \) conditional on the noisy representation:

\[
a = E[x|s] = \beta s + (1 - \beta)\mu. 
\]  
(34)

(This is of course the estimate that minimizes the mean squared error, under the constraint that the estimate must be a function of \( s \).)

The second equality in (34) holds if and only the variance of the observation error satisfies

\[
\frac{\nu^2}{\sigma^2} = \beta^{-1} - 1 > 0. 
\]  
(35)

The decision rule (34) then implies that the distribution of \( a \) conditional on \( x \) will be Gaussian, with the moments (32)–(33).

Comparison of (35) with (31) indicates that the optimal degree of noise in the representation \( s \) is given by

\[
\frac{\nu^2}{\sigma^2} = [2\sigma^2 \theta^{-1/2} - 1]^{-1},
\]

as stated in the text. This is an increasing function of the information cost parameter \( \theta \), that approaches zero (the limiting case of perfectly accurate representation, and hence perfectly accurate estimation of the state) as \( \theta \) approaches zero, and becomes unboundedly large (the limiting case of a completely uninformative information structure) as \( \theta \) approaches the upper bound \( 4\sigma^4 \) from below.

In the case that \( \theta \geq 4\sigma^4 \), instead, there is no solution to the Euler-Lagrange equations, and we can show that there is no interior solution to the optimization problem. Instead, as stated in the text, it is optimal to choose a completely uninformative information structure, and to choose the estimate \( a = \mu \) at all times. This is because in this case, one can show
that any information structure and estimation rule implies that

\[ V \equiv E[(a-x)^2] + \frac{\theta}{4} E[I(x)] \geq E[(x-\mu)^2] = \sigma^2, \]

with the lower bound achieved only in the case that \( a = \mu \) with probability 1.

To prove this, we begin by observing that the Cramér-Rao bound for a biased estimator \(^{34}\) implies that

\[ E[(a-x)^2|x] \geq \frac{(\bar{a}'(x))^2}{I(x)} + (\bar{a}(x) - x)^2, \]

where \( \bar{a}(x) \equiv E[a|x] \), and \( I(x) \) is the Fisher information. Thus

\[
E[(a-x)^2|x] + \frac{\theta}{4} I(x) \geq \frac{(\bar{a}'(x))^2}{I(x)} + \frac{\theta}{4} I(x) + (\bar{a}(x) - x)^2 \\
\geq \min_{I} \left\{ \frac{(\bar{a}'(x))^2}{I} + \frac{\theta}{4} I \right\} + (\bar{a}(x) - x)^2 \\
= \theta^{1/2} |\bar{a}'(x)| + (\bar{a}(x) - x)^2 \\
\geq 2\sigma^2 |\bar{a}'(x)| + (\bar{a}(x) - x)^2 \\
\geq 2\sigma^2 \bar{a}'(x) + (\bar{a}(x) - x)^2,
\]

where the next-to-last inequality follows from the assumption that \( \theta \geq 4\sigma^4 \). Taking the expected value under the prior \( q(x) \), it then follows that

\[ V \geq \int_{-\infty}^{\infty} q(x) [2\sigma^2 \bar{a}'(x) + (\bar{a}(x) - x)^2] dx. \quad (36) \]

We wish to obtain a lower bound for the integral on the right-hand side of (36). To do this, we solve for the function \( \bar{a}(x) \) that minimizes this integral, using the calculus of variations. Once again, we note that the integrand is a convex function of \( \bar{a} \) and \( \bar{a}' \), so that the first-order conditions are both necessary and sufficient for a minimum. The first-order conditions are given by the Euler-Lagrange equations

\[ 2q(x)(\bar{a}(x) - x) = 2\sigma^2 q'(x), \]

which have a unique solution \( \bar{a}(x) = \mu \) for all \( x \).

---

\(^{34}\)See Cover and Thomas (2006), p. 396.
Substituting this solution into the integral (36), we obtain the tighter lower bound

\[ V \geq \int_{-\infty}^{\infty} q(x) (x-\mu)^2 \, dx = \sigma^2. \]  

(37)

But this lower bound is achievable by choosing \( a = \mu \) with probability 1, regardless of the value of \( x \) (the optimal estimate in the case of a perfectly uninformative information structure). Hence a perfectly uninformative information structure is optimal for all \( \theta \geq 4\sigma^4 \).

This solution is not only one way of achieving the lower bound, it is the only way. It follows from the reasoning used to derive the lower bound for \( V \) that the lower bound can be achieved only if each of the weak inequalities holds as an equality. But the bound in (37) is equal to the bound in (36) only if \( \bar{a}(x) = \mu \) almost surely; thus optimality requires this. And the restriction that \( E[a|x] = \mu \) for a set of \( x \) with full measure implies that we must have

\[ E[(a-x)^2|x] = (x-\mu)^2 + \text{var}[a|x]. \]

This in turn implies that

\[ E[(a-x)^2] = E[(x-\mu)^2] + E[\text{var}[a|x]] = \sigma^2 + E[\text{var}[a|x]]. \]

Hence the lower bound can be achieved only if \( E[\text{var}[a|x]] = 0 \).

Given that the variance is necessarily non-negative, this requires that \( \text{var}[a|x] = 0 \) almost surely. This together with the requirement that \( E[a|x] = \mu \) almost surely implies that \( a = \mu \) almost surely. Hence optimality requires that \( a = \mu \) with probability 1, whenever \( \theta \geq 4\sigma^4 \).

C.5 Additional Definition and Lemmas

**Definition 1.** Let \( X^M \) be a sequence of state spaces, as described in section 5.3. A sequence of policies \( \{p_M \in \mathcal{P}(X^M)\}_{M \in \mathbb{N}} \) satisfies the “convergence condition” if:

i) The sequence satisfies, for some constants \( c_H > c_L > 0 \), all \( M \), and all \( i \in X^M \),

\[ \frac{c_H}{M+1} \geq e_i^T p_M \geq \frac{c_L}{M+1}. \]
ii) The sequence satisfies, for some constant $K_1 > 0$, all $M$, and all $i \in X^M \setminus \{0, M\}$,

$$M^3 \left| \frac{1}{2} (e_{i+1}^T + e_{i-1}^T - 2e_i^T) p_M \right| \leq K_1,$$

and

$$M^2 \left| \frac{1}{2} (e_M^T - e_{M-1}^T) p_M \right| \leq K_1$$
and

$$M^2 \left| \frac{1}{2} (e_1^T - e_0^T) p_M \right| \leq K_1.$$

**Definition 2.** Let \( \{p_M \in \mathcal{P}(X^M)\}_{M \in \mathbb{N}} \) be a sequence of probability distributions over the state spaces associated with Theorem 2. The interpolating functions \( \{\hat{p}_M \in \mathcal{P}([0, 1])\}_{M \in \mathbb{N}} \) are, for \( x \in \left[ \frac{1}{2(M+1)}, 1 - \frac{1}{2(M+1)} \right] \),

$$\hat{p}_M(x) = (M + 1)((M + 1)x + \frac{1}{2} - [(M + 1)x + \frac{1}{2}])e_{\lfloor (M+1)x+\frac{1}{2} \rfloor}^T p_M +$$

$$+ (M + 1)\left( \frac{1}{2} - (M + 1)x + [(M + 1)x + \frac{1}{2}] \right)e_{\lfloor (M+1)x+\frac{1}{2} \rfloor - 1}^T p_M,$$
and, for \( x \in \left[ 0, \frac{1}{2(M+1)} \right] \),

$$\hat{p}_M(x) = (M + 1)e_0^T q_M,$$
and, for \( x \in \left[ 1 - \frac{1}{2(M+1)}, 1 \right] \),

$$\hat{p}_M(x) = (M + 1)e_M^T q_M.$$

**Lemma 5.** Given a function \( p \in \mathcal{P}([0, 1]) \), define the sequence \( \{p_M \in \mathcal{P}(X^M)\}_{M \in \mathbb{N}} \),

$$e_i^T p_M = \int_{\frac{i}{M+1}}^{\frac{i+1}{M+1}} p(x) dx,$$
where \( X^M \) is the state space described in section 5.3. If the function \( p \) is strictly greater than zero for all \( x \in [0, 1] \), differentiable, and its derivative is Lipschitz continuous, then the sequence \( \{p_M \in \mathcal{P}(X^M)\}_{M \in \mathbb{N}} \) satisfies the convergence condition, and satisfies, for some constant \( K > 0 \), all \( M \), and all \( i \in X^N \setminus \{0, M\} \),

$$M^2 \left| \ln \left( \frac{1}{2} (e_{i+1}^T + e_{i-1}^T) q_M \right) + \ln \left( \frac{1}{2} (e_{i-1}^T + e_i^T) q_M \right) - 2\ln(e_i^T q_M) \right| \leq K,$$
and
\[ M \ln \left( \frac{1}{2} (e_1^T + e_0^T)q_M - \ln(e_0^T q_M) \right) < K \]
and
\[ M \ln \left( \frac{1}{2} (e_M^T + e_{M-1}^T)q_M - \ln(e_M^T q_M) \right) < K. \]

**Proof.** See the technical appendix, C.8. □

**Lemma 6.** Let \( \{p_M \in \mathcal{P}(X^M)\}_{M \in \mathbb{N}} \) be a sequence of probability distributions over the state spaces associated with Theorem 2. If the sequence \( \{p_M \in \mathcal{P}(X^M)\}_{M \in \mathbb{N}} \) satisfies the convergence condition (Definition 1), then there exists a sub-sequence, whose elements we denote by \( n \), such that:

i) The interpolating functions (2) \( \hat{p}_n(x) \) converge point-wise to a differentiable function \( p(x) \in \mathcal{P}([0, 1]) \), whose derivative is Lipschitz-continuous, with \( p(x) > 0 \) for all \( x \in [0, 1] \),

ii) the following sum converges:
\[
\lim_{n \to \infty} n^2 \sum_{i \in X \setminus \{n\}} \{ g(e_i^T p_n) + g(e_{i+1}^T p_n) - 2g\left( \frac{1}{2} (e_i^T + e_{i+1}^T) p_n \right) \} = \frac{1}{4} \int_0^1 \left( \frac{p'(x)}{p(x)} \right)^2 dx,
\]
where \( g(x) = x \ln(x) \),

iii) for all \( a \in A \), \( \lim_{n \to \infty} u_{a,n}^T p_n = \int_0^1 u_a(x) p(x) dx \),

iv) and, if the sequence \( \{p_M \in \mathcal{P}(X^M)\}_{M \in \mathbb{N}} \) is constructed from some function \( \tilde{p}(x) \), as in Lemma 5, then \( p(x) = \tilde{p}(x) \) for all \( x \in [0, 1] \).

**Proof.** See the technical appendix, section C.9. □

**Lemma 7.** Let \( \pi_M(a) \in \mathcal{P}(A) \) and \( \{q_{a,M} \in \mathcal{P}(X^M)\}_{a \in A} \) denote optimal policies in the discrete state setting described in section 5.3. For each \( a \in A \), the sequence \( \{q_{a,N}\} \) satisfies the convergence condition (Definition 1).

**Proof.** See the technical appendix, section C.10. □
C.6 Proof of Theorem 2

By the boundedness of $\mathcal{P}(A)$, there exists a convergent sub-sequence of the optimal policy $\pi_n(a)$, which we also denote by $n$. Define

$$\pi(a) = \lim_{n \to \infty} \pi_n(a).$$

By Lemma 7, for all $a \in A$, each sequence of optimal policies $\{q_{a,n}\}$ satisfies the convergence condition (Definition 1). Therefore, by Lemma 6, each sequence of interpolating functions (2), $\{\hat{q}_{a,n}(x)\}$, has a convergent sub-sequence that converges to a differentiable function $q_a(x)$, whose derivative is Lipschitz continuous. We can construct a sub-sequence in which $\pi_n(a)$ and all $\{\hat{q}_{a,n}(x)\}$ converge by iteratively applying this argument. Pass to this subsequence.

We can write the discrete value function, using Lemma 2, and defining $g(x) = x \ln x$, as

$$V_N(q_n; n) = \max_{\{p_{x,n} \in \mathcal{P}(A)\}} \sum_{i \in X} \sum_{a \in A} e_a^T p_n \text{Diag}(q) u_n e_a$$

$$- \theta n^2 \sum_{a \in A} (e_a^T p_n q_n) \sum_{i=0}^{n-1} \left[ g\left( \frac{e_i^T q_{a,n}}{\hat{q}_{i,a,n}} \right) + g\left( \frac{e_{i+1}^T q_{a,n}}{\hat{q}_{i,a,n}} \right) \right]$$

$$+ \theta n^2 \sum_{i=0}^{n-1} \left[ g\left( \frac{e_i^T q_N}{\hat{q}_{i,a,N}} \right) + g\left( \frac{e_{i+1}^T q_N}{\hat{q}_{i,a,N}} \right) \right]$$

$$- \theta n^{-1} \sum_{i=0}^{n-1} (e_i^T q_n) D_{KL}(p_n e_i || p_n q_n).$$

We can re-arrange this to

$$V_N(q_n; n) = \max_{\{p_{x,n} \in \mathcal{P}(A)\}} \sum_{i \in X} \sum_{a \in A} e_a^T p_n \text{Diag}(q) u_n e_a$$

$$- \theta n^2 \sum_{a \in A} (e_a^T p q) \sum_{i=0}^{N-1} \left[ g(e_i^T q_{a,n}) + g(e_{i+1}^T q_{a,n}) - 2g\left( \frac{1}{2}(e_i^T + e_{i+1}^T) q_{a,n} \right) \right]$$

$$+ \theta n^2 \sum_{i=0}^{N-1} \left[ g(e_i^T q_n) + g(e_{i+1}^T q_n) - 2g\left( \frac{1}{2}(e_i^T + e_{i+1}^T) q_n \right) \right]$$

$$- \theta n^{-1} \sum_{i=0}^{N-1} (e_i^T q_N) D_{KL}(p_{i,n} || p_n q_n).$$
By Lemma 6 and the boundedness of the KL divergence,

\[
\lim_{n \to \infty} V_N(q_n; n) = \sum_{a \in \mathcal{A}} \pi(a) \int_0^1 u_a(x)q_a(x)dx \\
\quad - \frac{\theta}{4} \sum_{a \in \mathcal{A}} \{ \pi(a) \int_0^1 \frac{(q'_a(x))^2}{q_a(x)}dx + \frac{\theta}{4} \int_0^1 \frac{(q'(x))^2}{q(x)}dx \}.
\]

Suppose that \(\pi(a)\) and the \(q_a(x)\) functions do not maximize this expression (subject to the constraints stated in Theorem 2). Let \(\pi^*(a)\) and \(q^*_a(x)\) be maximizers. Define, for all \(n\),

\[
\tilde{\pi}_n(a) = \pi^*(a),
\]

\[
e_i^T \tilde{q}_{a,n} = \int_{\frac{i+1}{n+1}}^{\frac{i+1}{n+1}} q^*_a(x)dx.
\]

Note that, by construction, \(\tilde{q}_{a,n} \in \mathcal{P}(X^n)\) and \(\sum_{a \in \mathcal{A}} \tilde{\pi}_N(a)\tilde{q}_{a,n} = q_n\). That is, the constraints of the discrete-state problem are satisfied for all \(n\). Denote the value function under these policies as \(\tilde{V}_N(q_n; n)\).

Because of the constraints stated in Theorem 2, each \(q^*_a\) satisfies the conditions of Lemma 5, and therefore the sequence \(\tilde{q}_{a,n}\) satisfies the convergence condition for all \(a \in \mathcal{A}\). It follows by Lemma 6 that this sequence of policies delivers, in the limit, the value function \(V_N(q)\). If this function is strictly larger than \(\lim_{n \to \infty} V_N(q_n; n)\), there must exist some \(\bar{n}\) such that

\[
\tilde{V}_N(q_{\bar{n}}; \bar{n}) > V_N(q_{\bar{n}}; \bar{n}),
\]

contradicting optimality. Therefore, the functions \(q_a(x)\) and \(\pi(a)\) are maximizers.

It remains to show that

\[
\lim_{n \to \infty} \sum_{i=0}^{\lfloor xn \rfloor} e_i^T q_{a,n} = \int_0^x q_a(y)dy.
\]

Note that

\[
e_i^T q_{a,n} = (n + 1) \int_{\frac{i+1}{n+1}}^{\frac{i+1}{n+1}} \tilde{q}_{a,n}(\frac{2i + 1}{2(n+1)})dy,
\]
where \( \hat{q}_{a,n} \) is the function defined in Lemma 6. Therefore, the sum is equal to

\[
\sum_{i=0}^{\lfloor xn \rfloor} e_i^T q_{a,n} = \int_0^{\lfloor xn \rfloor + 1 \pi/2 + \frac{n+1}{2}} \hat{q}_{a,n}(\frac{(n+1)y + \frac{n+1}{2}}{n+1}) dy.
\]

By the boundedness of \( \hat{q}_{a,n} \) (which follows from the convergence condition) and the dominated convergence theorem,

\[
\lim_{n \to \infty} \int_0^{\lfloor xn \rfloor + 1 \pi/2 + \frac{n+1}{2}} \hat{q}(\frac{(n+1)y + \frac{n+1}{2}}{n+1}) dy = \int_0^x q_a(y) dy,
\]

as required.

### C.7 Proof of Lemma 4

We begin by observing that any information structure \( p \in \mathcal{P}_{\text{LipG}}(A) \) defines unconditional action frequencies \( \pi \in \mathcal{P}(A) \) and posteriors \( q_a \in \mathcal{P}_{\text{LipG}}([0,1]) \) satisfying (24), using definitions (25). And conversely, any unconditional action frequencies and posteriors satisfying (24) define an information structure, using definitions (26). Hence the set of candidate structures is the same in both problems, and the problems are equivalent if the two objective functions are equivalent as well. It is also easily seen that in each problem, the first term of the objective function is the expected value of the DM’s reward \( u(x,a) \), integrating over the joint distribution for \( (x,a) \). Hence it remains only to establish that the remaining terms of the objective function are equivalent as well.

Consider any information structure \( p \in \mathcal{P}_{\text{LipG}}(A) \) and the corresponding unconditional action frequencies and posteriors, and let \( x \) be any point at which \( q(x) > 0 \), and at which \( p_a(x) \) is twice differentiable for all \( a \) (and as a consequence, \( q_a(x) \) is twice differentiable for all \( a \) as well). (We note that, given the Lipschitz continuity of the first derivatives, the set of \( x \) for which this is true must be of full measure.) Then the fact that \( \sum_{a \in A} p_a(x) = 1 \) for all \( x \) implies that

\[
\sum_{a \in A} p_a''(x) = 0,
\]

and similarly, constraint (24) implies that

\[
\sum_{a \in A} \pi(a) q_a''(x) = q''(x).
\]
At any such point, the definition of the Fisher information implies that

\[ I_{Fisher}(x) = \sum_{a \in A} \left( \frac{p'_a(x)}{p_a(x)} \right)^2 \]

\[ = \sum_{a} p''_a(x) - \sum_{a \in A} p_a(x) \frac{\partial^2 \log p_a(x)}{\partial x^2} \]

\[ = -\frac{\pi(a)q_a(x)}{q(x)} \frac{\partial^2}{\partial x^2} \left[ \log \pi(a) + \log q_a(x) - \log q(x) \right] \]

\[ = \frac{1}{q(x)} \left[ \sum_{a \in A} \pi(a) \left( \frac{q'_a(x)}{q_a(x)} \right)^2 - \sum_{a \in A} \pi(a)q''_a(x) - \frac{(q'(x))^2}{q(x)} + q''(x) \right] \]

\[ = \frac{1}{q(x)} \left[ \sum_{a \in A} \pi(a) \left( \frac{q'_a(x)}{q_a(x)} \right)^2 - \frac{(q'(x))^2}{q(x)} \right] . \]

Here the first line is the definition of the Fisher information (given in the lemma), and the second line follows from twice differentiating the function \( \log p_a(x) \) with respect to \( x \). In the third line, the first term from the second line vanishes because of (38); the remaining term from the second line is rewritten using (26). The fourth line follows from the third line by twice differentiating each of the terms inside the square brackets with respect to \( x \). The fifth line then follows from (39).

Since this result holds for a set of \( x \) of full measure, we obtain expression

\[ \int_0^1 q(x)I_{Fisher}(x)dx = \sum_{a \in A} \pi(a) \int_0^1 \left( \frac{q'_a(x)}{q_a(x)} \right)^2 dx - \int_0^1 \frac{(q'(x))^2}{q(x)} dx \]

for the mean Fisher information. This shows that the information-cost terms in both objective functions are equivalent, and hence the two problems are equivalent, and have equivalent solutions.

### C.8 Proof of Lemma 5

**Proof.** The function \( p \) is strictly greater than zero, and continuous, and therefore attains a maximum and minimum on \([0, 1]\), which we denote with \( c_H \) and \( c_L \), respectively. By construction,

\[ e^T_i p_M \geq \frac{c_L}{M+1} \]

and likewise for \( c_H \), satisfying the bounds.
For all $i \in X^{M} \setminus \{M\}$,
\[
(e_{i+1}^{T} - e_{i}^{T})p_{M} = \int_{i \in M+1}^{i+1 \in M+1} (p(x + \frac{1}{M+1}) - p(x))dx
= \int_{i \in M+1}^{i+1 \in M+1} \int_{0}^{\frac{1}{M+1}} p'(x+y)dydx
\]
and therefore, letting $K_2$ be the maximum of the absolute value of $p'$ on $[0, 1]$ (which exists by the continuity of $p'$), we have
\[
|(e_{i+1}^{T} - e_{i}^{T})p_{M}| \leq \frac{1}{(M+1)^2}K_2,
\]
(40)
satisfying the convergence condition for the endpoints.

For all $i \in X^{M} \setminus \{0, M\}$,
\[
(e_{i+1}^{T} + e_{i-1}^{T} - 2e_{i}^{T})p_{M} = \int_{i \in M+1}^{i+1 \in M+1} (p(x + \frac{1}{M+1}) + p(x - \frac{1}{M+1}) - 2p(x))dx
= \int_{i \in M+1}^{i+1 \in M+1} \int_{0}^{\frac{1}{M+1}} (p'(x+y) - p'(x-y))dydx.
\]
Let $K_3$ denote the Lipschitz constant associated with $p'$. It follows that
\[
|(e_{i+1}^{T} + e_{i-1}^{T} - 2e_{i}^{T})p_{M}| \leq \frac{2K_3}{(M+1)^3}.
\]

Therefore, the convergence condition is satisfied for $K_1 = \max(\frac{1}{2}K_2, K_3)$.

By the concavity of the log function, and the inequality $\ln(x) \leq x - 1$,
\[
\ln(\frac{1}{2}(e_{i+1}^{T} + e_{i}^{T})p_{M}) + \ln(\frac{1}{2}(e_{i-1}^{T} + e_{i}^{T})p_{M}) \leq 2\ln(\frac{1}{2}(e_{i+1}^{T} + e_{i-1}^{T} + e_{i}^{T})p_{M})
\leq \frac{1}{2}(e_{i+1}^{T} + e_{i-1}^{T} - 2e_{i}^{T})p_{M}
\]
\[
\leq \frac{1}{2}(e_{i+1}^{T} + e_{i-1}^{T})p_{M}.
\]

Therefore, by the convergence condition we have established,
\[
\ln(\frac{1}{2}(e_{i+1}^{T} + e_{i}^{T})p_{M}) + \ln(\frac{1}{2}(e_{i-1}^{T} + e_{i}^{T})p_{M}) \leq \frac{(M+1)K_1}{M^3c_L} \leq \frac{2K_1}{M^2c_L}.
\]
By the inequality $-\ln\left(\frac{1}{x}\right) \leq x - 1$, we have

$$\ln\left(\frac{\frac{1}{2}(e_{i+1}^T + e_i^T) p_M}{e_i^T p_M}\right) + \ln\left(\frac{\frac{1}{2}(e_{i-1}^T + e_i^T) p_M}{e_i^T p_M}\right) \geq \frac{1}{2}(e_{i+1}^T - e_i^T) p_M + \frac{1}{2}(e_{i-1}^T - e_i^T) p_M.$$

We can rewrite this as

$$\ln\left(\frac{\frac{1}{2}(e_{i+1}^T + e_i^T) p_M}{e_i^T p_M}\right) + \ln\left(\frac{\frac{1}{2}(e_{i-1}^T + e_i^T) p_M}{e_i^T p_M}\right) \geq \frac{1}{2}(e_{i+1}^T - e_i^T) p_M - \frac{1}{2}(e_{i-1}^T - e_i^T) p_M,$$

and, using equation (40),

$$\frac{1}{2}(e_{i+1}^T - e_i^T) p_M \leq \frac{1}{2}(e_{i-1}^T - e_i^T) p_M \leq \frac{1}{2}(e_{i+1}^T - e_i^T) p_M - 1.$$
\[
\max\left(\frac{K_2}{c_L}, \frac{2K_1}{c_L} + \left(\frac{K_2}{2c_L}\right)^2\right).
\]

C.9 Proof of Lemma 6

Proof. We begin by noting that the functions \(\hat{p}_M(x)\) are absolutely continuous. Almost everywhere in \([\frac{1}{2(M+1)}, 1 - \frac{1}{2(M+1)}]\),

\[
\hat{p}_M'(x) = (M + 1)^2 (e^T [((M+1)x + \frac{1}{2}] - e^T [((M+1)x + \frac{1}{2}] - 1) p_M,
\]

and outside this region, \(\hat{p}_M'(x) = 0\). Let \(\tilde{p}_M'(x)\) denote the right-continuous Lebesgue-integrable function on \([0, 1]\) such that

\[
\hat{p}_M(x) = \hat{p}_M(0) + \int_0^x \tilde{p}_M'(y) dy,
\]

which is equal to \(\hat{p}_M'(x)\) anywhere the latter exists.

The total variation of \(\tilde{p}_M'(x)\) is equal to

\[
TV(\tilde{p}_M') = \sum_{i=1}^{M-1} (M + 1)^2 |(e^T_{i+1} + e^T_{i-1} - 2e^T_i)p_M| +
\]

\[
+ (M + 1)^2 |(e^T_M - e^T_{M-1})p_M| + (M + 1)^2 |(e^T_1 - e^T_0)p_M|.
\]

By the convergence condition,

\[
TV(\tilde{p}_M') \leq \frac{(M + 1)^3}{M^3} - 2K_1,
\]

and therefore the sequence of functions \(\tilde{p}_M'(x)\) has uniformly bounded variation.

For any \(1 - \frac{1}{2(M+1)} > x > y \geq \frac{1}{2(M+1)}\), the quantity

\[
|\tilde{p}_M'(x) - \tilde{p}_M'(y)| = (M + 1)^2 \sum_{i = \lfloor (M+1)x + \frac{1}{2} \rfloor}^{\lfloor (M+1)y + \frac{1}{2} \rfloor} |(e^T_{i+1} + e^T_{i-1} - 2e^T_i)p_M|
\]

\[
\leq \frac{(M + 1)^2 ((M + 1)(x - y) + 2)}{M^3} 2K_1.
\]

79
At the end points, for all $x \in [0, \frac{1}{2(M+1)}]$,

$$|\hat{p}'_{M} \left( \frac{1}{2(M+1)} \right) - \hat{p}'_{M}(x)| \leq \frac{2K_1}{M+1}.$$ 

and for all $x \in [1 - \frac{1}{2(M+1)}, 1]$,

$$|\hat{p}'_{M}(x) - \lim_{y \uparrow 1 - \frac{1}{2(M+1)}} \hat{p}'_{M}(y)| \leq \frac{2K_1}{M+1}.$$ 

By $\hat{p}'_{M}(0) = 0$, we have, for all $x \in [0, 1]$,

$$|\hat{p}'_{M}(x)| \leq \left( \frac{(M+1)^2((M+1)(1 - \frac{1}{2(M+1)}) + 2)}{M^3} + \frac{1}{M+1} \right) 2K_1,$$

proving that $\hat{p}'_{M}(x)$ is bounded uniformly in $M$ for all $x \in [0, 1]$.

Therefore Helly’s selection theorem applies. That is, there exists a sub-sequence, which we denote by $n$, such that $\hat{p}'_{n}(x)$ converges point-wise to some $p'(x)$. Moreover, by the point-wise convergence of $\hat{p}'_{M}$ to $p'$, for all $x > y$,

$$|p'(x) - p'(y)| \leq 2K_1(x - y),$$

meaning that $p'$ is Lipschitz-continuous. By the fact that $p'(0) = 0$, this implies that $|p'(x)| \leq 2K_1$ for all $x \in [0, 1]$.

By the convergence condition, $c_L \leq \hat{p}_{n}(0) \leq c_H$. Therefore, there exists a convergent sub-sequence. We now use $n$ to denote the sub-sequence for which $\lim_{n \to \infty} \hat{p}_{n}(0) = p(0)$ and for which $\hat{p}'_{n}(x)$ converges point-wise to $p'(x)$. By the dominated convergence theorem, for all $x \in [0, 1]$,

$$\lim_{n \to \infty} \hat{p}_{n}(x) = \lim_{n \to \infty} \{ \hat{p}_{n}(0) + \int_{0}^{x} \hat{p}'_{n}(y)dy \} = p(0) + \int_{0}^{x} p'(y)dy.$$ 

Define the function $p(x) = p(0) + \int_{0}^{x} p'(y)dy$ for all $x \in [0, 1]$. By the convergence conditions, this function is bounded, $0 < c_L \leq p(x) \leq c_H$, by construction it is differentiable, and its derivative is Lipschitz continuous. Moreover,

$$\int_{0}^{1} p(x)dx = 1,$$
and therefore \( p \in \mathcal{P}([0, 1]) \).

Next, consider the limiting cost function. We have, using the function \( g(x) = x \ln x \) and Taylor-expanding,

\[
g(y) = g(x) + g'(x)(y-x) + \frac{1}{2} g''(cy + (1-c)x)(y-x)^2
\]

for some \( c \in (0, 1) \). Therefore,

\[
g(e_i^T p_M) + g(e_{i+1}^T p_M) - 2g\left(\frac{1}{2}(e_i^T + e_{i+1}^T)p_M\right) =
\]

\[
\frac{1}{8} g''(c_1 e_i^T p_M + (1-c_1)\frac{1}{2}(e_i^T + e_{i+1}^T)p_M)((e_{i+1}^T - e_i^T)p_M)^2
\]

\[
+ \frac{1}{8} g''(c_2 e_i^T p_M + (1-c_2)\frac{1}{2}(e_i^T + e_{i+1}^T)p_M)((e_{i+1}^T - e_i^T)p_M)^2
\]

for constants \( c_1, c_2 \in (0, 1) \). Note that, by the boundedness \( \hat{p}_M(x) \) from below, \( e_i^T p_M \geq (M+1)^{-1} c_L \) for all \( i \in X^M \). It follows that

\[
g''(c_1 e_i^T p_M + (1-c_1)\frac{1}{2}(e_i^T + e_{i+1}^T)p_M) = \frac{1}{c_1 e_i^T p_M + (1-c_1)\frac{1}{2}(e_i^T + e_{i+1}^T)p_M} \leq (M+1)c_L^{-1}.
\]

Therefore,

\[
0 \leq g(e_i^T p_M) + g(e_{i+1}^T p_M) - 2g\left(\frac{1}{2}(e_i^T + e_{i+1}^T)p_M\right) \leq \frac{(M+1)c_L^{-1}}{4}((e_{i+1}^T - e_i^T)p_M)^2.
\]

By construction,

\[
e_i^T p_M = \frac{1}{(M+1)} \hat{p}_M(\frac{2i+1}{2(M+1)}).
\]

Therefore,

\[
(M+1)(g(e_i^T p_M) + g(e_{i+1}^T p_M) - 2g\left(\frac{1}{2}(e_i^T + e_{i+1}^T)p_M\right)) =
\]

\[
g(\hat{p}_M(\frac{2i+1}{2(M+1)})) + g(\hat{p}_M(\frac{2i+3}{2(M+1)})) - 2g(\hat{p}_M(\frac{2i+2}{2(M+1)})).
\]

and

\[
g(e_i^T p_M) + g(e_{i+1}^T p_M) - 2g\left(\frac{1}{2}(e_i^T + e_{i+1}^T)p_M\right) \leq \frac{c_L^{-1}}{4(M+1)}(\hat{p}(\frac{2i+3}{2(M+1)}) - \hat{p}(\frac{2i+1}{2(M+1)}))^2.
\]
By the boundedness of \( \hat{p}_M'(x) \),
\[
g(\hat{p}(\frac{2i+1}{2(M+1)})) + g(\hat{p}(\frac{2i+3}{2(M+1)})) - 2g(\hat{p}(\frac{2i+2}{2(M+1)})) \leq \frac{B}{(M+1)^2}
\]
for some finite bound \( B \).

Writing the limiting cost as an integral, and switching to the sub-sequence \( n \) defined above,
\[
n^2 \sum_{i \in X^n \setminus \{n\}} \{g(e_i^T p_n) + g(e_{i+1}^T p_n) - 2g(\frac{1}{2}(e_i^T + e_{i+1}^T)p_n)\} =
\]
\[
\frac{n^3}{n+1} \int_0^1 \{g(\hat{p}_n(\frac{2|nx| + 1}{2(n+1)}) + g(\hat{p}_n(\frac{2|nx| + 3}{2(n+1)})) - 2g(\hat{p}_n(\frac{2|nx| + 2}{2(n+1)}))\}dx.
\]

By the bound above,
\[
\frac{n^3}{n+1} \int_0^1 \{g(\hat{p}_n(\frac{2|nx| + 1}{2(n+1)}) + g(\hat{p}_n(\frac{2|nx| + 3}{2(n+1)})) - 2g(\hat{p}_n(\frac{2|nx| + 2}{2(n+1)}))\} dx \leq \frac{n^3}{(n+1)^3} \int_0^1 B \ dx.
\]

Applying the dominated convergence theorem,
\[
\lim_{n \to \infty} n^2 \sum_{i \in X^n \setminus \{n\}} \{g(e_i^T p_n) + g(e_{i+1}^T p_n) - 2g(\frac{1}{2}(e_i^T + e_{i+1}^T)p_n)\} =
\]
\[
\int_0^1 \lim_{n \to \infty} n^3 \{g(\hat{p}_n(\frac{2|nx| + 1}{2(n+1)}) + g(\hat{p}_n(\frac{2|nx| + 3}{2(n+1)})) - 2g(\hat{p}_n(\frac{2|nx| + 2}{2(n+1)}))\} dx.
\]

By the Taylor expansion above,
\[
\lim_{n \to \infty} \frac{n^3}{n+1} \{g(\hat{p}_n(\frac{2|nx| + 1}{2(n+1)}) + g(\hat{p}_n(\frac{2|nx| + 3}{2(n+1)})) - 2g(\hat{p}_n(\frac{2|nx| + 2}{2(n+1)}))\} =
\]
\[
\lim_{n \to \infty} \frac{1}{8n+1} \{g''(\cdot) + g''(\cdot)\} \left(\hat{p}_n(\frac{2|nx| + 3}{2(n+1)}) - \hat{p}_n(\frac{2|nx| + 1}{2(n+1)})\right)^2.
\]

By definition,
\[
(n+1)(\hat{p}_n(\frac{2|nx| + 3}{2(n+1)}) - \hat{p}_n(\frac{2|nx| + 1}{2(n+1)})) = \hat{p}_n'(\frac{2|nx| + 2}{2(n+1)})
\]

82
and
\[
\lim_{n \to \infty} g''(\hat{p}_n(\frac{2|nx|+3}{2(n+1)}) - \hat{p}_n(\frac{2|nx|+2}{2(n+1)})) = \frac{1}{p(x)},
\]
with \(c_n \in (0, 1)\) for all \(n\), and therefore
\[
\lim_{n \to \infty} \frac{n^3}{n+1} \{g(\hat{p}_n(\frac{2|nx|+1}{2(n+1)})) + g(\hat{p}_n(\frac{2|nx|+3}{2(n+1)})) - 2g(\hat{p}_n(\frac{2|nx|+2}{2(n+1)}))\} = \\
\lim_{n \to \infty} \frac{1}{4} \frac{(p'(x))^2}{p(x)},
\]
proving the second claim.

Turning to the third claim, recall that, by definition,
\[
e_i^T u_{a,M} = \frac{\int_{\tilde{x}_M}^{e_i+1} u_a(x) q(x) dx}{\int_{\tilde{x}_M}^{e_i+1} q(x) dx}.
\]
We define the function, for \(x \in [0, 1]\), as
\[
u_{a,M}(x) = e_i^T \left[ e_i \left( M+1 \right) \right] u_{a,M},
\]
and let \(u_{a,M}(1) = e_i^T u_{a,M}\). We also define the function
\[
\tilde{x}_M(x) = \frac{2\lfloor (M+1)x \rfloor + 1}{2(M+1)}.
\]
By construction, \(\hat{p}_M(\tilde{x}_M(x)) = (M+1)e_i^T e_i \left[ (M+1)x \right] p_{a,M}\) for all \(x \in [0, 1]\), and equals \(e_i^T p_{a,M}\) for \(x = 1\). Therefore,
\[
u_{a,M}^T p_M = \sum_{i \in X^M} (e_i^T u_{a,M})(e_i^T p_M) = \\
\int_0^1 \hat{p}_M(\tilde{x}_M(x)) u_{a,M}(x) dx.
\]
By the measurability of \(u_a(x)\),
\[
\lim_{M \to \infty} u_{a,M}(x) = u_a(x).
\]
Therefore, by the boundedness of utilities and the dominated convergence theorem,

$$\lim_{n \to \infty} u_{a,n}^T p_n = \int_0^1 p(x) u_a(x) dx.$$ 

Finally, suppose that, for all $M$

$$e_i^T p_{a,M} = \int_{\frac{i-1}{M+1}}^{\frac{i}{M+1}} \tilde{p}(x) dx.$$ 

It follows that $\lim_{n \to \infty} \hat{p}_{a,n}(x) = \tilde{p}(x)$ for all $x \in [0, 1]$, and therefore $\tilde{p}(x) = p(x)$. 

\[\square\]

**C.10 Proof of Lemma 7**

*Proof.* We begin by noting that the conditions given for the function $q(x)$ satisfy the conditions of Lemma 5, and therefore the sequence $q_M$ satisfies the convergence condition. We will use the constants $c_H$ and $c_L$ to refer to its bounds,

$$\frac{c_H}{M+1} \geq e_i^T q_M \geq \frac{c_L}{M+1},$$

and the constants $K_1$ and $K$ to refer to the constants described by convergence condition and Lemma 5 for the sequence $q_M$. By the convention that $q_{a,M} = q_M$ if $\pi_M(a) = 0$, $q_{a,M}$ also satisfies the convergence condition whenever $\pi_M(a) = 0$.

The problem of size $M$ is

$$V_N(q_M; M) = \max_{\pi_M \in \mathcal{P}(A), \{q_{a,M} \in \mathcal{P}(X^M)\}_{a \in A}} \sum_{a \in A} \pi_M(a) (u_{a,M}^T q_{a,M}) - \theta \sum_{a \in A} \pi_M(a) D_N(q_{a,M} || q_M; M)$$

subject to

$$\sum_{a \in A} \pi_M(a) q_{a,M} = q_M,$$

where

$$D_N(q_{a,M} || q_M; \rho, M) = M^2 (H_N(q_{a,M}; 1, M) - H_N(q_M; 1, M)) + M^{-1} (H^S(q_{a,M}; M) - H^S(q_M; M))$$

and

$$H_N(q; 1, M) = - \sum_{i=0}^{M-1} \tilde{q}_i H^S(q_i).$$
Let $u_M$ denote that $|X^M| \times |A|$ matrix whose columns are $u_{a,M}$. Using Lemma 3, we can rewrite the problem as

\[
V_N(q_M; M) = \max_{\{p_{i,M} \in \mathcal{P}(A)\}_{i \in M}, a \in A} \sum_{i=0}^{M-1} e_a^T P_M \text{Diag}(q) u_M e_a \\
- \theta M^2 \sum_{i=0}^{M-1} (e_i^T q_M) D_{KL}(P_{i,M}||p_{i,M}(e_i^T q_M + p_{i+1,M}(e_{i+1}^T q_M)) \\
- \theta M^2 \sum_{i=1}^{M} (e_i^T q_M) D_{KL}(P_{i,M}||p_{i,M}(e_i^T q_N + p_{i-1,M}(e_{i-1}^T q_M)) \\
- \theta M^{-1} \sum_{i=0}^{M-1} (e_i^T q_M) D_{KL}(P_{i,M}||p_{MqM}).
\]

The FOC for this problem is, for all $i \in [1, M - 1]$ and $a \in A$ such that $e_a^T p_{i,M} > 0$,

\[
e_i^T u_{a,M} - \theta M^2 \ln\left(\frac{e_a^T p_{i,M}(e_i^T + e_{i+1}^T q_M)}{e_a^T (p_{i,M}(e_i^T q_M) + p_{i+1,M}(e_{i+1}^T q_M))}\right) \\
- \theta M^2 \ln\left(\frac{e_a^T p_{i,M}(e_i^T + e_{i-1}^T q_M)}{e_a^T (p_{i,M}(e_i^T q_M) + p_{i-1,N}(e_{i-1}^T q_M))}\right) - \theta M^{-1} \ln\left(\frac{e_a^T p_{i,M}}{e_a^T p_{MqM}}\right) - e_i^T \kappa_M = 0,
\]

where $\kappa_M \in \mathbb{R}^{M+1}$ are the multipliers (scaled by $e_i^T q_M$) on the constraints that $\sum_{a \in A} e_a^T p_{i,M} = 1$ for all $i \in X$. Defining $e_i^T q_M = e_{i+1}^T q_M = 0$, and defining $p_{-1,M}$ and $p_{M+1,M}$ in arbitrary fashion, we can recover this FOC for all $i \in X$.

Rewriting the FOC in terms of the posteriors, and again defining $e_i^T q_{a,M} = e_{i+1}^T q_{a,M} = 0$, for any $a$ such that $\pi_M(a) > 0$,

\[
e_i^T (u_{a,M} - \kappa_M) = \theta M^2 \ln\left(\frac{(e_i^T q_{a,M})(1 + e_{i+1}^T q_M)}{(e_{i+1} + e_i)^T q_{a,M}}\right) + \theta M^2 \ln\left(\frac{(e_i^T q_{a,N})(1 + e_{i-1}^T q_N)}{(e_{i-1} + e_i)^T q_{a,N}}\right) \\
+ \theta M^{-1} \ln\left(\frac{e_a^T p_{i,M}}{e_a^T p_{MqM}}\right) \\
= -\theta M^2 \ln(1 + \frac{e_{i+1}^T q_{a,M}}{e_i^T q_{a,M}}) + \theta M^2 \ln(1 + \frac{e_{i+1}^T q_M}{e_i^T q_M}) - \theta M^2 \ln(1 + \frac{e_{i-1}^T q_{a,M}}{e_i^T q_{a,M}}) \\
+ \theta M^2 \ln(1 + \frac{e_{i-1}^T q_M}{e_i^T q_M}) + \theta M^{-1} \ln\left(\frac{e_i^T q_{a,M}}{e_i^T q_M}\right),
\]
which can be rewritten as
\[
e^T_i (u_{a,M} - \kappa_M) = -\theta M^2 (\ln(\frac{1}{2} (e^T_{i+1} + e^T_i) q_{a,M}) + \ln(\frac{1}{2} (e^T_{i-1} + e^T_i) q_{a,M}) - (2 + M^{-3}) \ln(e^T_i q_{a,M}))
\]
\[+ \theta M^2 (\ln(\frac{1}{2} (e^T_{i+1} + e^T_i) q_{M}) + \ln(\frac{1}{2} (e^T_{i-1} + e^T_i) q_{M}) - (2 + M^{-3}) \ln(e^T_i q_{M})).
\]

(41)

Our analysis proceeds by analyzing this first-order condition.

We next describe a series of lemmas that use this first-order condition to establish various bounds, which will ultimately be used to establish the bounds required by the convergence condition. As part of the proof, we find it useful to consider the interpolating functions \(\hat{q}_{a,M}(x)(2)\) constructed from \(q_{a,M}\). We define from these interpolating functions the function
\[
l_{a,N}(x) = (M+1)(\ln(\hat{q}_{a,M}(x)) - \ln(\hat{q}_{a,M}(x - \frac{1}{2(M+1)})))
\]
on \(x \in [\frac{1}{2(M+1)}, 1]\), observing that, for any \(i \in X^M \setminus \{0\}\),
\[
l_{a,M}(\frac{2i+1}{2(M+1)}) = (M+1) \ln(\frac{(M+1)e^T_i q_{a,M}}{2(M+1)(e^T_i + e^T_{i-1}) q_{a,M}}),
\]
and for any \(i \in X^M \setminus \{M\}\),
\[
l_{a,M}(\frac{2i+2}{2(M+1)}) = (M+1) \ln(\frac{1}{2}(M+1)(e^T_i + e^T_{i+1}) q_{a,M}}{(M+1)e^T_i q_{a,M}}).
\]

\(\square\)

**Lemma 8.** For all \(M \in \mathbb{N}\) and \(i \in X^M \setminus \{0,M\}\), \(e^T_i \kappa_M \leq B_\kappa\) for some positive constant \(B_\kappa\).

**Proof.** See the technical appendix, section C.11. \(\square\)

**Lemma 9.** For all \(M \in \mathbb{N}\) and \(i \in \{0,M\}\), \(|e^T_i \kappa_M| \leq B_0\) for some positive constant \(B_0\), and
\[
\ln(\frac{\frac{1}{2}(e^0_0 + e^1_1) q_{a,M}}{e^0_0 q_{a,M}}) \leq M^{-1} B_1
\]
and
\[
\ln(\frac{e^M_M q_{a,M}}{\frac{1}{2}(e^M_M + e^M_{M-1}) q_{a,M}}) \geq -M^{-1} B_1.
\]
for some positive constant $B_1$.

**Proof.** See the technical appendix, section C.12.

**Lemma 10.** For all $M \in \mathbb{N}$ and $j \in \{2, 3, \ldots, 2M + 1\}$, and some positive constant $B_1$,

$$|l_{a,N}(\frac{j}{2(M+1)})| \leq B_1.$$  

**Proof.** See the technical appendix, section C.13. The proof uses the previous two lemmas.

**C.10.1 Proof that $\frac{c_i H}{M+1} \geq e_i^T q_{a,M} \geq \frac{c_i}{M+1}$**

We next apply the above lemmas to prove that the first part of the convergence condition is satisfied. Begin by observing that there must exist some $\tilde{i}_{a,M} \in X^M$ such that $e_{\tilde{i}_{a,M}}^T q_{a,M} \geq \frac{1}{N+1}$, implying that

$$\ln((M+1)e_{\tilde{i}_{a,M}}^T q_{a,M}) \geq 0.$$  

By the definition of $l_{a,M}$, for any $i \in X^M \setminus \{0\}$,

$$l_{a,M}(\frac{2i+1}{2(M+1)}) + l_{a,M}(\frac{2i}{2(M+1)}) = (M+1)\ln(\frac{(M+1)e_i^T q_{a,M}}{(M+1)e_{i-1}^T q_{a,M}}).$$

For any $i > \tilde{i}_{a,M}$, using Lemma 10,

$$\ln((M+1)e_i^T q_{a,M}) = \ln((M+1)e_{\tilde{i}_{a,M}}^T q_{a,M}) + \sum_{j=\tilde{i}_{a,M}+1}^{i} \ln(\frac{(M+1)e_j^T q_{a,M}}{(M+1)e_{j-1}^T q_{a,M}})$$

$$= \ln((M+1)e_{\tilde{i}_{a,M}}^T q_{a,M}) + \frac{1}{M+1} \sum_{j=\tilde{i}_{a,M}+1}^{i} l_{a,M}(\frac{2j+1}{2(M+1)}) + l_{a,N}(\frac{2j}{2(M+1)})$$

$$\geq -\frac{1}{M+1} \sum_{j=\tilde{i}_{a,M}+1}^{i} 2B_j$$

$$\geq -2B_j.$$  

Similarly, for any $i < \tilde{i}_{a,M}$,

$$\ln((M+1)e_i^T q_{a,M}) = \ln((M+1)e_{\tilde{i}_{a,M}}^T q_{a,M}) + \sum_{j=i+1}^{\tilde{i}_{a,M}} \ln(\frac{(N+1)e_j^T q_{a,N}}{(N+1)e_{j-1}^T q_{a,N}}).$$

87
Therefore, for any $i < \tilde{r}_{a,M}$,

$$\ln((M+1)e_i^Tq_{a,M}) \geq -\sum_{j=i}^{\tilde{r}_{a,M}} \ln\left(\frac{(M+1)e_j^Tq_{a,M}}{(M+1)e_{j-1}^Tq_{a,M}}\right),$$

and thus, using Lemma 10, for all $i \in X^M$, 

$$\ln((M+1)e_i^Tq_{a,M}) \geq -2B_i.$$ 

Repeating this argument, there must be some $\hat{r}_{a,M}$ such that $e_{\hat{r}_{a,M}}^Tq_{a,M} \leq M^{-1}$, and using the bounds on $l_{a,M}$ in similar fashion yields 

$$\ln((M+1)e_{\hat{r}_{a,M}}^Tq_{a,M}) \leq 2B_i.$$ 

It follows that, for all $M, a \in A$ such that $\pi_{M}(a) > 0$, and $i \in X^M$, 

$$\frac{\exp(2B_i)}{(M+1)} \geq e_i^Tq_{a,M} \geq \frac{\exp(-2B_i)}{M+1},$$

(demonstrating that $q_{a,M}$ satisfies the first part of the convergence condition.

C.10.2 Proof that $M^3|\frac{1}{2}(e_{i+1}^T - e_i^T)q_{a,M}| \leq K_1$

We start by proving a bound on $(M+1)^2|\frac{1}{2}(e_{i+1}^T - e_i^T)q_{a,M}|$.

Using Lemma 10, and a Taylor expansion of $\ln(1+x)$, for some $c \in (0,1)$, for any $i \in X^M \setminus \{M\}$, 

$$|l_{a,M}(\frac{2i+2}{2(M+1)})| = |(M+1)\ln\left(\frac{\frac{1}{2}(M+1)(e_i^T + e_{i+1}^T)q_{a,M}}{(M+1)e_i^Tq_{a,M}}\right)|$$

$$= \frac{(M+1)|\frac{1}{2}(e_{i+1}^T - e_i^T)q_{a,M}|}{e_i^Tq_{a,M} + \frac{1}{2}(e_{i+1}^T - e_i^T)q_{a,M}}$$

$$\leq B_i,$$

and therefore, by the bound on $e_i^Tq_{a,M}$, for any $i \in X^M \setminus \{M\}$, 

$$(M+1)^2|\frac{1}{2}(e_{i+1}^T - e_i^T)q_{a,M}| \leq B_i\exp(-2B_i).$$ (43)
Returning to the first-order condition, for \( i \in X^N \setminus \{0,N\} \), and using the bounds on utility and on the terms involving \( q_M \),

\[
e_i^T \kappa_M \geq -\bar{u} - \theta K + \theta M^{-1} \ln \left( \frac{e_i^T q_M}{e_i^T q_{a,M}} \right) + \theta M^2 (\ln \left( \frac{1}{2} (e_{i+1}^T + e_i^T) q_{a,M} \right) + \ln \left( \frac{1}{2} (e_{i-1}^T + e_i^T) q_{a,M} \right) - 2 \ln \left( e_i^T q_{a,M} \right)).
\]

We have

\[
M^{-1} \ln \left( \frac{e_i^T q_M}{e_i^T q_{a,M}} \right) \geq M^{-1} \ln \left( \frac{cL}{\exp(2B_i)} \right),
\]

and therefore

\[
e_i^T \kappa_M \geq -\bar{u} - \theta K + M^{-1} \ln \left( \frac{cL}{\exp(2B_i)} \right) + \theta M^2 (\ln \left( \frac{1}{2} (e_{i+1}^T + e_i^T) q_{a,M} \right) + \ln \left( \frac{1}{2} (e_{i-1}^T + e_i^T) q_{a,M} \right)).
\]

Using the mean-value theorem, for some \( c_1 \in (0,1) \),

\[
\ln \left( \frac{1}{2} (e_{i+1}^T + e_i^T) q_{a,M} \right) = \ln \left( 1 + \frac{1}{2} (e_{i+1}^T - e_i^T) q_{a,M} \right) = \frac{e_i^T q_M}{e_i^T q_{a,M}} - c_1 \frac{1}{2} (e_{i+1}^T - e_i^T) q_{a,M},
\]

and likewise

\[
\ln \left( \frac{1}{2} (e_{i-1}^T + e_i^T) q_{a,M} \right) = \frac{1}{2} (e_{i-1}^T - e_i^T) q_{a,M} \left( 1 - \frac{1}{2} c_2 e_i^T q_{a,M} + \frac{1}{4} c_1 e_{i+1}^T q_{a,M} \right)
\]

for some \( c_2 \in (0,1) \). Therefore,

\[
e_i^T \kappa_M \geq -\bar{u} - \theta K + M^{-1} \ln \left( \frac{cL}{\exp(2B_i)} \right) + \theta M^2 \left( \frac{1}{2} (e_{i+1}^T - e_i^T) q_{a,M} \right) + \frac{1}{2} (e_{i-1}^T - e_i^T) q_{a,M} \left( \frac{1}{2} c_2 e_i^T q_{a,M} + \frac{1}{2} c_1 e_{i+1}^T q_{a,M} \right).\]
Multiplying through,

\[
[(1 - \frac{1}{2}c_1)e_i^T q_{a,M} + \frac{1}{2}c_1e_{i+1}^T q_{a,M}][e_i^T \kappa_M + \bar{u} + \theta K - M^{-1}\ln\left(\frac{c_L}{\exp(2B_l)}\right)]
\]

\[
\geq \theta M^2 \left(\frac{1}{2}(e_{i+1}^T - e_i^T)q_{a,M} + \frac{1}{2}(e_{i-1}^T - e_i^T)q_{a,M}\right)\left(1 - \frac{1}{2}c_1e_i^T q_{a,M} + \frac{1}{2}c_1e_{i+1}^T q_{a,M}\right).
\]

\[
\geq \theta M^2 \left(\frac{1}{2}(e_{i+1}^T + e_{i-1}^T - 2e_i^T)q_{a,M} + \frac{1}{2}(e_{i-1}^T - e_i^T)q_{a,M}\right)\left(1 - \frac{1}{2}c_1e_i^T q_{a,M} + \frac{1}{2}c_2e_{i-1}^T q_{a,M}\right).
\]

Using equations (42) and (43),

\[
[(1 - \frac{1}{2}c_1)e_i^T q_{a,M} + \frac{1}{2}c_1e_{i+1}^T q_{a,M}][e_i^T \kappa_M + \bar{u} + \theta K - M^{-1}\ln\left(\frac{c_L}{\exp(2B_l)}\right)]
\]

\[
\geq \theta M^2 \left(\frac{1}{2}(e_{i+1}^T + e_{i-1}^T - 2e_i^T)q_{a,M} - B_l\exp(2B_l)\left(\frac{2B_l\exp(2B_l)}{(M+1)^2}\right)\right)
\]

\[
\geq \theta M^2 \left(\frac{1}{2}(e_{i+1}^T + e_{i-1}^T - 2e_i^T)q_{a,M} - \theta \frac{2B_l^2M^2\exp(6B_l)}{(M+1)^3}\right).
\]

Summing over \(a\), weighted by \(\pi_N(a)\), and applying Lemma 5,

\[
(e_i^T \kappa_M + \bar{u} + \theta K - M^{-1}\ln\left(\frac{c_L}{\exp(2B_l)}\right)) \geq -\theta \frac{K_i^\dagger M + \frac{2B_l^2M^2\exp(6B_l)}{(M+1)^3}}{M+1}
\]

\[
\geq -\theta c_L^{-1}(2K_1 + 2B_l^2\exp(6B_l)).
\]

Therefore, \(|e_i^T \kappa_N|\) is bounded below by some \(B_k^+ > 0\) for all \(i \in X^N\) (recalling that this was shown for \(i \in \{0, N\}\) in Lemma 9 and in the other direction in Lemma 8).

It also follows, using equation (42), that

\[
\theta M^2(M+1)\left(\frac{1}{2}(e_{i+1}^T + e_{i-1}^T - 2e_i^T)q_{a,M}\right) \leq \exp(2B_l)(B_k^+ + \bar{u} + \theta K - M^{-1}\ln\left(\frac{c_L}{\exp(2B_l)}\right))
\]

\[
+ \theta \frac{2B_l^2M^2\exp(6B_l)}{(M+1)^2},
\]

which establishes one side of the bound on \(|\frac{1}{2}(e_{i+1}^T + e_{i-1}^T - 2e_i^T)q_{a,M}|\).

Rewriting the FOC (equation (41)) and using Lemma 5 and the boundedness of the
utility and the bound on $|e^T_i \kappa_N|$, 

$$-B_k^+ - \bar{u} - \theta K - \theta M^{-1} \ln \left( \frac{e^T_i q_M}{e^T_i q_{a,M}} \right) \leq \theta M^2 \left( \ln \left( \frac{1}{2} (e^T_{i+1} + e^T_i) q_{a,M} \right) + \ln \left( \frac{1}{2} (e^T_{i-1} + e^T_i) q_{a,M} \right) - 2 \ln(e^T_i q_{a,M}) \right).$$

By equation (42),

$$M^{-1} \ln \left( \frac{e^T_i q_M}{e^T_i q_{a,M}} \right) \leq -B_l \frac{c_H}{\exp(-2B_l)} \ln \left( \frac{1}{2} (e^T_{i+1} + e^T_i + 2e^T_i) q_{a,M} \right),$$

and therefore, by the concavity of the log function,

$$-B_k^+ - \bar{u} - \theta K - \theta M^{-1} \ln \left( \frac{c_H}{\exp(-2B_l)} \right) \leq 2 \theta M^2 \ln \left( \frac{1}{3} \frac{(e^T_{i+1} + e^T_i + 2e^T_i) q_{a,M}}{e^T_i q_{a,M}} \right).$$

By the inequality $\ln(x) \leq x - 1$,

$$-B_k^+ - \bar{u} - \theta K - \theta M^{-1} \ln \left( \frac{c_H}{\exp(-2B_l)} \right) \leq 2 \theta M^2 \left( \ln \left( \frac{1}{3} \frac{(e^T_{i+1} + e^T_i - 2e^T_i) q_{a,M}}{e^T_i q_{a,M}} \right) \right),$$

and therefore, using the lower bound on $e^T_i q_{a,M}$ (equation (42)),

$$-B_k^+ - \bar{u} - \theta K - \theta M^{-1} \ln \left( \frac{c_H}{\exp(-2B_l)} \right) \leq \theta M^2 (M + 1) \frac{1}{2} (e^T_{i+1} + e^T_i - 2e^T_i) q_{a,M},$$

which proves the other side of the bound.

**C.10.3 Proof that $M^2 |\frac{1}{2} (e^T_i - e^T_0) q_{a,M}| \leq K_1$**

By Lemma 10,

$$-B_l \leq (M + 1) \ln \left( \frac{1}{2} (e^T_0 + e^T_i) q_{a,M} \right) \leq B_l.$$

Using the mean-value theorem, for some $c \in (0, 1)$,

$$\ln \left( \frac{1}{2} (e^T_0 + e^T_i) q_{a,M} \right) = \frac{1}{2} \frac{(e^T_i - e^T_0) q_{a,M}}{(1 - \frac{1}{2} c) e^T_0 q_{a,M} + \frac{1}{2} c e^T_i q_{a,M}}.$$
Therefore, by equation (42),
\[
\frac{\exp(2B_i)}{(M+1)^2} B_i \geq \frac{1}{2} (e^T_i - e^T_0) q_{a,M} \geq -\frac{\exp(2B_i)}{(M+1)^2} B_i,
\]
proving the bound. The proof for the other endpoint is identical.

C.11 Proof of Lemma 8

First, using Lemma 5, for all \(i \in X^M \setminus \{0, M\}\), observe that
\[
M^2 \left| \ln(\frac{1}{2} (e^T_{i+1} + e^T_i) q_{M}) + \ln(\frac{1}{2} (e^T_{i-1} + e^T_i) q_{M}) - 2 \ln(e^T_i q_{M}) \right| \leq K.
\]

Rewriting the FOC (equation (41)) and using this bound,
\[
e^T_i \kappa_M \leq e^T_i u_{a,M} + \theta K + \theta M^{-1} \ln(e^T_i q_{M})
\]
\[
+ \theta M^2 \left( \ln(\frac{1}{2} (e^T_{i+1} + e^T_i) q_{a,M}) + \ln(\frac{1}{2} (e^T_{i-1} + e^T_i) q_{a,M}) - (2 + M^{-3}) \ln(e^T_i q_{a,M}) \right).
\]

By the boundedness of the utility function, this can be rewritten as
\[
e^T_i \kappa_M \leq \bar{u} + \theta K - \theta M^2 (\ln(\frac{1}{2} (e^T_{i+1} + e^T_i) q_{a,M}) + \ln(\frac{1}{2} (e^T_{i-1} + e^T_i) q_{a,M})) - \theta M^{-1} \ln(\frac{e^T_i q_{a,M}}{e^T_i q_{M}}).
\]

By the concavity of the log function,
\[
\ln(\frac{1}{2} (e^T_{i+1} + e^T_i) q_{a,M}) + \ln(\frac{1}{2} (e^T_{i-1} + e^T_i) q_{a,M}) + M^{-3} \ln(e^T_i q_{M}) \leq
\]
\[
(2 + M^{-3}) \ln(\frac{1}{2(2 + M^{-3}) (e^T_{i+1} + e^T_{i-1} + 2 e^T_i) q_{a,M}} + \frac{M^{-3}}{2 + M^{-3}} e^T_i q_{M}).
\]

It follows that
\[
e^T_i \kappa_N \leq \bar{u} + \theta K + (2 + M^{-3}) \theta M^2 \ln(\frac{\frac{1}{2(2 + M^{-3})} (e^T_{i+1} + e^T_{i-1} + 2 e^T_i) q_{a,M} + \frac{M^{-3}}{2 + M^{-3}} e^T_i q_{M}}{e^T_i q_{a,M}}).
\]
Exponentiating,

\[(e_i^T q_{a,M}) \exp(-\frac{1}{2 + M^{-3}} \theta^{-1} M^{-2} (\bar{u} + \bar{\theta} K - e_i^T \kappa_M)) \leq \]

\[\frac{1}{2(2 + M^{-3})} (e_{i+1}^T + e_{i-1}^T + 2e_i^T) q_{a,M} + \frac{M^{-3}}{2 + M^{-3}} e_i^T q_M.\]

Summing over a, weighted by \(\pi_N(a)\),

\[(e_i^T q_M) \exp(-\frac{1}{2 + M^{-3}} \theta^{-1} M^{-2} (\bar{u} + \bar{\theta} K - e_i^T \kappa_M)) \leq \]

\[\frac{1}{2(2 + M^{-3})} (e_{i+1}^T + e_{i-1}^T + 2e_i^T) q_M + \frac{M^{-3}}{2 + M^{-3}} e_i^T q_M.\]

Taking logs,

\[-\frac{1}{2 + M^{-3}} \theta^{-1} M^{-2} (\bar{u} + \bar{\theta} K - e_i^T \kappa_M) \leq \ln\left(\frac{\frac{1}{2(2 + M^{-3})} (e_{i+1}^T + e_{i-1}^T + 2e_i^T) q_M + \frac{M^{-3}}{2 + M^{-3}} e_i^T q_M}{e_i^T q_M}\right)\]

\[\leq \ln\left(1 + \frac{M^{-3}}{2 + M^{-3}} + \frac{1}{2 + M^{-3}} \frac{K_1 M^{-3}}{c_L M^{-1}}\right),\]

where the last step follows by Lemma 5, recalling that \(c_L\) is the lower bound on \(q(x)\). We have

\[e_i^T \kappa_N \leq 3 \theta M^2 \ln\left(1 + \frac{M^{-3}}{2 + M^{-3}} + \frac{1}{2 + M^{-3}} \frac{K_1}{c_L M^{-2}}\right) + \bar{u} + \bar{\theta} K\]

\[\leq \bar{u} + \theta K + \frac{3 \theta M^{-1}}{2 + M^{-3}} + \frac{3 \theta}{2 + M^{-3}} K_1\]

\[\leq \bar{u} + \theta K + \frac{3 \theta}{2} + \frac{3 \theta K_1}{2} c_L.\]

where the second step follows by the inequality \(\ln(1 + x) < x\) for \(x > 0\).
## C.12 Proof of Lemma 9

For the lower end point, the FOC (equation (41)) can be simplified to

\[ e_0^T (u_{a,M} - \kappa_M) = -\theta M^2 (\ln \left( \frac{1}{2} (e_1^T + e_0^T)q_{a,M} \right) + \ln \left( \frac{1}{2} \right) - (1 + M^{-3}) \ln (e_0^T q_{a,M})) \]

\[ + \theta M^2 (\ln \left( \frac{1}{2} (e_1^T + e_0^T)q_M \right) + \ln \left( \frac{1}{2} \right) - (1 + M^{-3}) \ln (e_0^T q_M)). \]

Rearranging this,

\[ \theta^{-1} M^{-2} e_0^T (u_{a,M} - \kappa_M) + \ln \left( \frac{1}{2} (e_1^T + e_0^T)q_{a,M} \right) = \]

\[ (1 + M^{-3}) \ln \left( \frac{e_0^T q_{a,M}}{e_0^T q_M} \right) + \ln \left( \frac{1}{2} (e_1^T + e_0^T)q_M \right). \]

Exponentiating,

\[ \frac{1}{2} (e_1^T + e_0^T)q_{a,M} \exp (\theta^{-1} M^{-2} e_0^T (u_{a,M} - \kappa_M)) = \left( \frac{e_0^T q_{a,M}}{e_0^T q_M} \right)^{1+M^{-3}} \frac{1}{2} (e_1^T + e_0^T)q_M. \]

By the boundedness of the utility function,

\[ \frac{1}{2} (e_1^T + e_0^T)q_{a,M} \exp (\theta^{-1} M^{-2} (\bar{u} - e_0^T \kappa_M)) \geq \left( \frac{e_0^T q_{a,M}}{e_0^T q_M} \right)^{1+M^{-3}} \frac{1}{2} (e_1^T + e_0^T)q_M. \]

Taking a sum over \( a \), weighted by \( \pi(a) \), and applying Jensen’s inequality,

\[ \frac{1}{2} (e_1^T + e_0^T)q_M \exp (\theta^{-1} M^{-2} (\bar{u} - e_0^T \kappa_M)) \geq \frac{1}{2} (e_1^T + e_0^T)q_M, \]

and therefore

\[ e_0^T \kappa_M \leq \bar{u}. \]

Observing that

\[ M^{-1} \ln \left( \frac{e_0^T q_{a,M}}{e_0^T q_M} \right) \leq M^{-1} \ln \left( \frac{M}{c_L} \right) \leq M^{-1} \left( \frac{M}{c_L} - 1 \right) \leq c_L^{-1}, \]  \hspace{1cm} (44)\]

we have

\[ \theta^{-1} M^{-2} e_0^T (u_{a,M} - \kappa_M) + \ln \left( \frac{1}{2} (e_1^T + e_0^T)q_{a,M} \right) \leq M^{-2} c_L^{-1} + \ln \left( \frac{e_0^T q_{a,M}}{e_0^T q_M} \right) + \ln \left( \frac{1}{2} (e_1^T + e_0^T)q_M \right). \]
Exponentiating,
\[
\frac{1}{2}(e_1^T + e_0^T)q_{a,M} \exp(\theta^{-1}M^{-2}(-\theta c_L^{-1} + e_0^T(u_{a,M} - \kappa_M))) \leq (\frac{e_T^T q_{a,M}}{e_0 q_M}) \frac{1}{2}(e_1^T + e_0^T)q_M
\]

Using the boundedness of the utility function, then taking a sum over \(a\), weighted by \(\pi(a)\),
\[
\frac{1}{2}(e_1^T + e_0^T)q_{a,M} \exp(\theta^{-1}M^{-2}(-\theta c_L^{-1} - \bar{u} - e_0^T \kappa_M))) \leq \frac{1}{2}(e_1^T + e_0^T)q_M.
\]

Therefore,
\[
e_0^T \kappa_M \geq -\bar{u} - \theta c_L^{-1},
\]
and thus
\[
|e_0^T \kappa_M| \leq B_0
\]
for \(B_0 = \bar{u} + \theta c_L^{-1}\). A similar argument applies to the other end-point \(e_T^T \kappa_M\).

Using the bound on utility and equation (44), the FOC requires that
\[
\ln(\frac{1}{2}(e_1^T + e_0^T)q_{a,M}) \leq \theta^{-1}M^{-2}(\bar{u} + B_0 + \theta c_L^{-1}) + \ln(\frac{1}{2}(e_1^T + e_0^T)q_M).
\]

By Lemma 5, it follows that
\[
\ln(\frac{1}{2}(e_1^T + e_0^T)q_{a,M}) \leq \theta^{-1}M^{-2}(\bar{u} + B_0 + \theta c_L^{-1}) + M^{-1}K,
\]
and therefore the constraint with \(B_1 = K + \theta^{-1}(\bar{u} + B_0 + \theta c_L^{-1})\) is satisfied.

Similarly, the FOC for the highest state is
\[
\theta^{-1}M^{-2}e_M^T(u_{a,M} - \kappa_M) + \ln(\frac{1}{2}(e_M^T + e_{M-1}^T)q_{a,M}) =
\]
\[
(1 + M^{-3})\ln(e_M^Tq_{a,M}) + \ln(\frac{1}{2}(e_M^T + e_{M-1}^T)q_M),
\]
and therefore
\[
\ln(\frac{1}{2}(e_M^T + e_{M-1}^T)q_{a,M}) \leq \theta^{-1}M^{-2}(\bar{u} + B_0 + \theta c_L^{-1}) + \ln(\frac{1}{2}(e_M^T + e_{M-1}^T)q_M),
\]

95
implying that
\[ \ln\left( \frac{1}{2}(e^T_{M} + e^T_{M-1})q_{a,M} \right) \leq \theta^{-1}M^{-2}(\bar{u} + B_0 + \theta c_L^{-1}) + M^{-1}K, \]
and therefore
\[ \ln\left( \frac{e^T_{M}q_{a,M}}{\frac{1}{2}(e^T_{M} + e^T_{M-1})q_{a,M}} \right) \geq -M^{-1}B_1. \]

C.13 Proof of Lemma 10

The first-order condition is, for any \( i \in X^M \setminus \{0,M\} \) can be re-written using the function \( l_{a,M} \) (and the function \( l_M \), defined from \( \hat{q}_M \) along the same lines) as
\[
e^T_i (\kappa_M - u_{a,M}) + \theta M^{-1}\ln\left( \frac{e^T_i q_{a,M}}{e^T_i q_M} \right) = \theta \frac{M^2}{(M+1)}(l_{a,M}(\frac{2i+2}{2(M+1)}) - l_{a,M}(\frac{2i+1}{2(M+1)}))
- \theta \frac{M^2}{(M+1)}(l_M(\frac{2i+2}{2(M+1)}) - l_M(\frac{2i+1}{2(M+1)})).
\]

Note that
\[
\theta M^{-1}\ln\left( \frac{e^T_i q_{a,M}}{e^T_i q_M} \right) \leq \theta M^{-1}\ln\left( \frac{1}{c_L(M-1)} \right) \leq \theta M^{-1}\left( \frac{M}{c_L} - 1 \right) \leq \theta c_L^{-1}.
\]

By Lemma 5 and Lemma 8 and the bound on utility,
\[
\theta \frac{M^2}{(M+1)}(l_{a,M}(\frac{2i+2}{2(M+1)}) - l_{a,M}(\frac{2i+1}{2(M+1)})) \leq B_\kappa + \bar{u} + \theta K + \theta c_L^{-1}.
\]

We also have, for all \( i \in X^M \setminus \{M\} \)
\[
\frac{M^2}{M+1}(l_{a,M}(\frac{2i+3}{2(M+1)}) - l_{a,M}(\frac{2i+2}{2(M+1)}))
= M^2(\ln\left( \frac{(M+1)e^T_{i+1}q_{a,M}}{\frac{1}{2}(M+1)(e^T_{i+1} + e^T_i)q_{a,M}} \right) - \ln\left( \frac{1}{2}(M+1)(e^T_i + e^T_{i+1})q_{a,M} \right))
\leq 0,
\]

96
by the concavity of the log function. Observe also that, by Lemma 9,

\[ l_{a,M}(\frac{2}{2(M+1)}) = (M + 1) \ln(\frac{1}{e_{0}q_{a,M}}) \leq \frac{M + 1}{M} B_{1}. \]

It follows that, for all \( j \in \{2, 3, \ldots, 2M + 1\}, \)

\[ l_{a,M}(\frac{j}{2(M+1)}) = l_{a,M}(\frac{2}{2(M+1)}) + \sum_{k=2}^{j-1} (l_{a,M}(\frac{k+1}{2(N+1)}) - l_{a,M}(\frac{k}{2(M+1)})) \leq \frac{M + 1}{M} B_{1}. \]

Similarly, for all \( j \in \{2, 3, \ldots, 2M + 1\}, \)

\[ l_{a,M}(\frac{2M + 1}{2(M+1)}) = l_{a,M}(\frac{j}{2(M+1)}) + \sum_{k=j}^{2M} (l_{a,M}(\frac{k+1}{2(M+1)}) - l_{a,M}(\frac{k}{2(M+1)})). \]

Observing that

\[ -l_{a,M}(\frac{2M + 1}{2(M+1)}) = -\ln(\frac{(M+1)e_{M}^{T}q_{a,M}}{\frac{1}{2}(M+1)(e_{M}^{T} + e_{M-1}^{T})q_{a,M}}) \leq \frac{M + 1}{M} B_{1}, \]

using Lemma 9,

\[ -l_{a,M}(\frac{j}{2(M+1)}) \leq \theta^{-1}(B_{K} + \bar{u} + \theta K + \theta c_{L}^{-1}) \frac{M + 1}{M^{2}} (2M - j + 1) + \frac{M + 1}{M} B_{1}. \]

It follows that, for all \( j \in \{2, 3, \ldots, 2M + 1\}, \)

\[ |l_{a,N}(\frac{j}{2(N+1)})| \leq \theta^{-1}(B_{K} + \bar{u} + \theta K + \theta c_{L}^{-1}) \frac{M + 1}{M^{2}} (2M - 1) + \frac{M + 1}{M} B_{1} \]

\[ \leq 4 \theta^{-1}(B_{K} + \bar{u} + \theta K + \theta c_{L}^{-1}) + 2B_{1}. \]
